hour at 80° to 85°, and when cold the excess of nitric acid is removed; the residue is a homogeneous crystalline mass of *o-p*-dinitrotoluene, solidifying at 69·5°. To convert this into the trinitro-derivative, it is dissolved by gently heating with four times its weight of 95–96 per cent. sulphuric acid, and while keeping cool is mixed with $\frac{1}{2}$ times its weight of 90–92 per cent. nitric acid; it is then digested at between 90–95°, with occasional stirring, until the evolution of gas ceases in about four or five hours. The operation is then stopped, and when the product is cool the excess of nitric acid is separated from it; the residue, after washing with hot water and very dilute soda, without further purification, solidifies at 79° to an almost white, radiating crystalline mass, which by recrystallisation from hot alcohol yields trinitrotoluene in brightly sparkling crystals, melting at 81·5°. 100 parts of dinitrotoluene yield 105 parts of the trinitro-derivative. 1:2:1:6 Trinitrotoluene can also be obtained from ordinary commercial dinitrotoluene, melting between 60°–64°, but when this is used the reaction is more violent; 10 per cent. more nitric acid is required and 10 per cent. less product obtained. It should be borne in mind when washing trinitrotoluene that it is not quite insoluble in hot water, and moreover that it is decomposed by dilute alkalis or alkaline carbonates.—D. A. L.

Action of Benzyl Chloride on Meta-xylidine. Jablen-Gonnet. Bull. Soc. Chim. 1891, 6, 21–22.

BENZYL chloride acts on meta-xylidine at 160°–165° C. to form the benzyl compound—

a yellow liquid, boiling at 200°–210° C., insoluble in water, soluble in alcohol and in benzene. The product forms unstable salts, readily decomposed by water and which are soluble in alcohol. Alkyl iodides and acetyl chloride react with benzyl meta-xylidine to form alkyl and acetyl compounds respectively, which are under investigation.

—C. A. K.

A New Method of Preparing Amido-alizarin. C. Lauth. Bull. Soc. Chim. 1891, 6, 836.

BETS-AMIDO-ALIZARIN may be readily prepared by the action of dimethylaniline on nitro-alizarin. One part of nitro-alizarin is dissolved in four parts of dimethylaniline, and either one part of syrupy dimethylaniline hydrochloride or 0·75 part of hydrochloric acid is added. The mixture is gradually heated to 150° C. on an oil-bath, and maintained at that temperature until a test-drop, when dissolved in caustic soda, forms a pure blue solution. The operation is then arrested, and the mass is washed with warm dilute hydrochloric acid to remove the dimethylaniline. The crystalline residue consists of impure amido-alizarin. It may be obtained quite pure by re-solution in caustic soda and re-precipitation by hydrochloric acid. The reduction of nitro-alizarin may be effected by dimethylaniline alone, although not so readily, as well as by aniline itself in presence of an excess of sulphuric acid.—H. T. P.

PATENTS.

The Manufacture and Production of Improved Dyestuffs suitable for Dyeing Vegetable Fibre with or without a Mordant. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 4513, March 13, 1891. (Second Edition.) *6d.*

It has long been known (Beyer and Kegel, Ger. Pat. 38,310, 1885) that certain safranines, on diazotisation and combination with naphthol sulphonic acids, yield azo-compounds. Owing to their being unsuitable for dyeing purposes, the patent was abandoned. If, however, a diazotised safranine be combined with α - or β -naphthol, the azo-compound thus formed is converted into a valuable colouring matter by treating it with an acid, preferably hydrochloric or acetic acid. The safranines which yield good results are: Phenosafranine, Safranine T (obtained by oxidising a mixture of molecular proportions of tolylene diamine,

o-toluidine, and aniline), and Safranine A S (obtained by oxidising *p*-amidodimethylaniline, *o*-toluidine, and *p*-toluidine). The following example illustrates the method employed:—Dissolve 7 kilos. of Safranine T in 700 litres of water, cool to 0°, and diazotise by the addition of 2 kilos. of sodium nitrite in 20 litres of water and 23 kilos. of hydrochloric acid of 30 per cent. HCl. The solution thus obtained is run into 3 kilos. of β -naphthol dissolved in 165 litres of water and 25 kilos. of caustic soda-lye containing 35 per cent. of NaOH. After stirring for several hours, the blackish-violet precipitate formed is filtered off, washed, and pressed. To convert it into a colouring matter it is suspended in 400 litres of water, and 46 kilos. of hydrochloric acid are added. The hydrochloric acid salt formed is then filter-pressed and used preferably as a paste. The colouring matters obtained from the various safranines yield different shades, varying from dark violet to indigo blue. They can be employed either with or without mordants, and are fast to washing and light.—T. A. L.

The Manufacture and Production of New Mordant-dyeing Colouring Matters related to the Rosaniline Series. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 4688, March 16, 1891. (Second Edition.) *8d.*

AN extension of the processes described in Eng. Pat. 4850 of 1884 (this Journal, 1885, 201) and of Eng. Pat. 5038 of 1884 (this Journal, 1885, 279). It has been discovered that by condensing certain hydroxy compounds with tetramethyl- or tetra-ethyl-diamidobenzophenone compounds, new bodies are produced, which by reason of their hydroxy groups are capable of combining with metallic mordants to give a variety of shades. The following dihydroxy compounds give good results:—(1:2) Dihydroxynaphthalene, (2:3) dihydroxynaphthalene (Eng. Pat. 15,803 of 1890; this Journal, 1891, 762), (2:7 or 2:2') dihydroxynaphthalene, pyrogallol.—T. A. L.

Manufacture of New Colouring Matters from Naphthyl-glycines. E. v. Portheim, Prague, Bohemia. Eng. Pat. 21,919, December 15, 1891. *6d.*

DIRECT dyeing cotton colouring matters are obtained by combining tetrazo-compounds of the diphenyl series with α - and β -naphthyl-glycines (O. Jolles, Ber. 22, 2372). The colours and properties of several of these dyestuffs are given in the following table:—

Diazotised.	Combined with	Colour.	Water.	Spirit.
Benzidine	α -glycine	Blue-red	Soluble	Soluble
Benzidine	β -glycine	"	Insoluble	"
Toluidine	α -glycine	Red	Soluble	"
Toluidine	β -glycine	Blue-red	Insoluble	"
<i>o</i> -Toluidine	β -glycine	Red	"	"
Benzidine sulphonic	α -glycine	Blue	Soluble	"
Benzidine sulphonic	β -glycine	"	Insoluble	"
Benzidine sulphonic acid ..	α -glycine	Blue-red	Soluble	"

A New Manufacture of Colouring Matters. J. Muray, London. From "La Société L. Durand, Huguenin et Cie," Bâle, Switzerland. Eng. Pat. 22,623, December 28, 1891.

Blue colouring matters for mordanted wool are produced by condensing galloxyaniline with trimethylamine, isobutylamine, amylamine, diamylamine, dipropylamine, and diethylamine, the first three under similar conditions to those described in Eng. Pat. 18,526 of 1890 (this Journal, 1891, 133), that is, in a concentrated aqueous solution on the water-bath. The other amines are employed in an anhydrous condition, the condensation with dry galloxyaniline also taking place on the water-bath.—T. A. L.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Improvements in Turkey-Red Dyeing. T. Baldensperger. Bull. Soc. Ind. de Rouen, 1891, 399.

In order to overcome the difficulties experienced in dyeing piece-goods with alizarin the author has proposed the following plan for dyeing them in the jigger. The prepared pieces first pass through the jigger, which is filled with cold water, to which a little lime-salts have been added. The solution is then heated to 50 °C., and a solution of alizarin in ammonia added in 2 or in 4 portions. The pieces are allowed to soak for half an hour, during which time the solution is heated to boiling, and then kept at the boil for a quarter of an hour longer. The bath is completely exhausted and the fabric dyed after 10 turns. The alizarin solution consists of 10 kilos. of 20 per cent. alizarin dissolved in 40 litres of water, and 1 kilo. of ammonia. The red obtained by this treatment is brighter and purer than that got without using ammonia, whilst 1 per cent. less alizarin reckoned on the weight of the material can be employed, since the ammonia solution has greater covering power. Attempts to employ a solution of alizarin in lime-water were unsatisfactory. The process can doubtless be employed for violet, garnet red, and other colours obtained in alizarin dyeing as well as in Turkey-red dyeing.—C. A. K.

Action of Water on Basic Salts of Copper. G. Rousseau and G. Tite. Compt. Rend. 1891, 113, 191—193.

PATENTS.

Improvements in Means and Method of Dyeing or Colouring Wool, Silk, Hair, Fur, Feathers, and other Animal or Vegetable Fibres or Plain Cut Pile, Raised Pile, or Looped Fabrics composed thereof. H. A. Foster, Queensbury, and J. Frost, Huddersfield. Eng. Pat. 478, January 10, 1891.

THE materials specified in the title are coloured by impregnation with a soluble salt of lead "or other metallic salt whose sulphide gives the desired colour or shade," and treatment with hydrogen sulphide, in the gaseous state or in aqueous solution, or with a solution of an alkaline sulphide. A design "or ornamental effect" is then produced on them by printing a thickened solution of hydrogen dioxide. To produce coloured effects dyes are added to the hydrogen dioxide mixture, and the printed material

steamed, if necessary, to fix the dye; or the material may be dyed red, yellow, blue, or green, before or after being coloured with the lead sulphide, and then be printed with the suitably thickened hydrogen dioxide.—E. B.

Process for Clarifying and Bleaching Tannin Extracts or Tanning Liquors. A. Foelsing, Düsseldorf, Germany. Eng. Pat. 4385, March 11, 1891.

Tan. liquors obtained by the extraction of such tanning materials as chestnuts, oak-bark, and divi divi, are brought to a density corresponding to 4 B. at 17½ °C., and drawn off into a tank; to every 10,000 litres of such tanning-liquor, 500 grms. of oxalic acid, and 2 kilos. of "sodic chloride," dissolved separately, are added. The liquid is then heated to 60 °C. and subjected to electrolysis.

"The electric current, besides decomposing the oxalic acid and sodic chloride, produces between the two poles a voluminous deposit which consists chiefly of resin, cellulose, and colouring matter, that is to say, substances other than tannin."

The electrodes may be made of platinum wire netting mounted in frames. The strength of the current depends on the quantity of liquid to be clarified, and the time in which the clarification is to take place.—A. G. B.

Improvements in the Manufacture of Alizarin Colours, and in the Method of Employing same in the Process of Dyeing. H. N. F. Schaeffer, Lowell, U.S.A. Eng. Pat. 20,010, November 18, 1891.

A soluble mixture or compound of alizarin is prepared by drying the commercial paste and mixing one part of it by weight with two parts of borax. On the addition of hot water to this mixture, a perfect solution of the alizarin is produced, the latter, in the inventor's opinion, becoming combined with both the acid and base of the borax, forming a definite sodium boro-alizarate. The solution thus obtained may be employed at once in dyeing, the fibre being impregnated with it, and the mordanting salt subsequently applied, or "may and preferably will be" evaporated to dryness and stored ready for use or packed for transport.

The colours produced by the interaction of sodium boro-alizarate and a mordanting salt are more brilliant and intense than those usually obtained in dyeing.

Instead of alizarin, anthrapurpurin and its homologues and allied dyestuffs may be employed in the above process.

—E. B.

VII.—ACIDS, ALKALIS, AND SALTS.

The Action of the Alkaline Bases on the Solubility of Salts of the Alkalix. R. Engel. Bull. Soc. Chim. 1891, 6, 15—17.

The author has previously examined the action of carbon dioxide on the solubility of certain neutral carbonates, and that of hydrochloric acid on the solubility of a large number of metallic chlorides, and has shown that one molecule of hydrochloric acid precipitates one molecule of monovalent and half a molecule of divalent chlorides from solution in all cases where the chloride does not combine chemically with the hydrochloric acid. The action of the hydrates of potassium and sodium on the solubility of their respective

chlorides is, that one molecule of the hydrate precipitates half a molecule of the chloride from its saturated solution; or that the precipitation of one molecule of the salt is effected by one molecule of the oxide K_2O or Na_2O . Tabulated results are given showing that the above relationship, although not absolutely correct, is approximately so with solutions containing varying amounts of the chloride and the hydrate. In the case of very soluble salts, such as iodide or nitrate of potassium, the precipitation is more rapid, and does not always amount to one molecule of the salt for one molecule of the hydrate. In the case of sodium nitrate, one molecule of sodium hydrate precipitates 0.71 molecules of the salt.—C. A. K.

The Action of Ammonia on the Solubility of Ammonium Chloride. R. Engel. Bull. Soc. Chim. 1891, 6, 17.

THE presence of ammonia at first hardly decreases the solubility of ammonium chloride at all and then increases it, as shown by the results obtained. This in the opinion of the author points to the formation of compounds of ammonia with ammonium chloride such as have been described by Troost.—C. A. K.

Action of Water on Basic Salts of Copper. G. Rousseau and G. Tite. Compt. Rend. 1891, 113, 191—193.

WATER transforms a number of neutral metallic salts into basic salts, and in some cases the oxide is formed, as in the case of antimony chloride and of certain borates. The authors have ascertained that both basic acetates of copper are transformed completely to oxide on heating with water in sealed tubes at 160° C. for 20 hours. Basic sulphate is completely transformed into oxide by heating with water at 240° to 250° for about 50 hours. Basic chloride was slightly decomposed only after 48 hours' heating at 210° to 260° C., and basic phosphate showed no change on heating for several days at 275°.—T. L. B.

New Crystalline Oxychlorides of Iron. G. Rousseau. Compt. Rend. 1891, 113, 542—544.

PATENTS.

Improvements in Apparatus connected with the Manufacture of Sulphate of Ammonia. R. Dempster and J. Dempster, Manchester. Eng. Pat. 12,661, August 13, 1890.

WITH a view of conveniently removing the sulphate of ammonia a pump is placed within the saturator, the suction pipe extended to the bottom of this vessel, and the delivery pipe connected to the drainers.

The patentees state they make no claim to anything described by Wilton in Eng. Pat. 19,225 of 1889 (this Journal, 1890, 623).—K. E. M.

Improvements in or Appertaining to Apparatus for the Manufacture of Carbonates of Soda. J. J. Howitt, Runcorn. Eng. Pat. 3657, February 28, 1891.

FOR carbonating ammoniated brine the patentee makes use of a high tower with perforated floors, through which two long vertical rods are passed. By means of these rods every floor may be raised up on one side, so as to enable the gases to pass through the column by a circuitous course. The water used for cooling the tower by trickling down outside is further used for cooling the carbonic acid before entering the tower.

The mother-liquor from the carbonating tower containing principally chloride of ammonium, is decomposed by lime and distilled in an ammonia-distilling tower, the main improvement of which consists in the substitution of

corrugated or ribbed caps for the ordinary plain hoods. The ammonia gases from the distilling tower pass through a cooling apparatus consisting of an annular chamber cooled inside and outside. It is supplied with a number of floors communicating with one another in such a manner as to cause the gases to pass through nearly the entire "annulus" before reaching the next floor. The ammonia, deprived of practically all steam, is then used for saturating fresh brine.

For details of the apparatus the drawings accompanying specification must be consulted.—K. E. M.

Improvements in the Treatment of a certain Material (Mineral) containing Phosphate of Lime for the Purpose of obtaining the Latter in a Highly Concentrated Condition as Dicalcic Phosphate, together with Certain Bye-Products. J. Simpson, Liverpool. Eng. Pat. 3785, March 3, 1891.

NATURAL phosphates or slags sufficiently free from lime are treated with hydrochloric acid of preferably 10° Tw. The resulting solution is decanted off from the insoluble residue. The latter may be used for the manufacture of cement, the former containing phosphate of lime is imperfectly neutralised with milk of lime, so that the precipitated dicalcium phosphate may not contain any free lime. The solution is now completely neutralised with lime, any excess of which may be utilised by an addition of fresh "phosphatic solution."—K. E. M.

Improvements in Apparatus used in the Manufacture of Sulphate of Ammonia. C. Marriott, Redcar. Eng. Pat. 4730, March 17, 1891.

THE invention consists in conveniently removing the sulphate of ammonia from the saturators by "self-acting means." From under a bell-shaped vessel, through which the ammonia gas enters the saturator, the sulphate of ammonia is continuously carried away by means of an endless apron entering the back of the saturator and travelling up its inclined front. The mother-liquor drains back into the separator. The crystals are removed from the apron by a scraper or other suitable means.—K. E. M.

Improvements in the Manufacture of Salt in Blocks or Cakes. P. J. B. Vincent, Paris, France. Eng. Pat. 6388, April 14, 1891.

SALT is fused and run into moulds to cool with a view of obtaining salt in blocks, which are said to be unaffected by climatic influences, and afford great facilities for transport.—K. E. M.

Improvements in the Production of Chlorine. J. Kolb, Lille, France. Eng. Pat. 6500, April 15, 1891.

THE pot gases, and especially the roaster gases from the salt-cake furnaces contain a certain proportion of sulphurous and sulphuric acids, which soon destroy the decomposing material used in the Deacon process. The mixed gases from the pot and the roaster may be purified by passing them through a series of externally heated cylinders charged with salt. As shown by Hargreaves, sulphurous acid is hereby converted into sodium sulphate, and chlorine or hydrochloric acid is given off. The gases, which still contain a small amount of sulphurous acid, are passed finally through a cylinder charged with bricks, previously saturated with magnesium chloride and copper chloride. The chlorine now evolved oxidises the sulphurous acid into sulphuric acid, which in its turn is retained by the bricks in the form of magnesium sulphate. Dealing with pot gases alone, the latter cylinder by itself is found efficient.

—H. A.

Improved Process and Apparatus for the Manufacture or Production of Bleaching Powder. C. Kellner, Vienna, Austria. Eng. Pat. 20,037, November 18, 1891.

The apparatus consists of a vessel provided with trays, with alternately placed slits. A vertical shaft passes through the vessel, carrying arms to pass over each tray. Dry slaked lime is introduced on the top shelf and is raked by means of the arms on the shelves below; in its downward movement it meets a current of previously washed chlorine which enters from below. "By this means the chlorine combines with the hydrate of lime, and chloride of lime or bleaching powder ready for use passes out at the bottom of the apparatus." A sheet of drawings illustrates the specification.—H. A.

Improved Process and Apparatus for the Manufacture or Production of Hydrogen and Chlorine from Hydrochloric Acid. C. Kellner, Vienna, Austria. Eng. Pat. 20,060, November 18, 1891.

The invention refers to the electrolysis of a hot solution of hydrochloric acid, whereby chlorine is given off at the anode and hydrogen at the cathode. The apparatus consists of a number of superposed receptacles made of acid-proof material and tightly joined together on the outer walls. Each of these receptacles is divided into longitudinal cells, formed by ribs extending both from the bottom and the top of the receptacles, and either meeting (in which case the ribs are perforated), or else separated by means of interposed diaphragms. These cells contain horizontally placed electrodes, arranged in alternate order, and in such a way that all cells situated vertically over one another should contain a similar pair of electrodes. A solution of hydrochloric acid is introduced in the uppermost receptacle, and flowing through the compartments runs by means of a lateral overflow pipe or overflow wall into the receptacle below, and traversing this, overflows at the opposite end into another receptacle, by which means the acid is caused to circulate through the whole apparatus, leaving the bottom division as weak acid. The gases evolved flow in separate streams through ascension pipes, connecting the respective superposed cells; these pipes are placed at the alternate ends of the cells, thus forcing the gases to take an opposite course to that of the liquid. The liquid is heated by means of indirect steam, conveyed in a coil of lead piping.

The description is given of a round apparatus, composed of superposed receptacles, each of which is divided by an annular rib (attached to the bottom of the next higher receptacle) into an inner circular chamber and an outer annular one, containing the respective electrodes.

In a modified apparatus the electrodes are placed vertically in a common trough, and the alternate rows of anodes and cathodes are separated from one another by means of perforated partitions. The electrodes are fixed to a supporting bar which forms a gas-tight joint with each cell. The hydrochloric acid enters the apparatus through a false bottom, under which it is heated with steam; it ascends through the cells and leaves through two lateral openings on the upper part of the vessel. The gases evolved are led away by means of ascension pipes, which pass finally through the top bar.

Two sheets of drawings accompany the specification.

—H. A.

Improvements in the Manufacture of Chlorine from Hydrochloric Acid Gas. "La Société A. R. Péchiney and Cie," Salindres, France. Eng. Pat. 22,320, December 21, 1891. By Internat. Conv. July 2, 1891.

INSTEAD of passing a mixture of hydrochloric acid gas and air (or oxygen, or either of these) through the cast-iron tubular apparatus, as used in the Deacon—or in the De Wilde and Reichler process—the inventors propose to pass the gases through any of the well-known hot blast stoves of Cowper-Siemens, Whitwell, and others. It is expected that a higher temperature with less wear and tear on the apparatus will be attained, as also the possibility of using the cheaper decomposing substances, such as De Wilde and Reichler's mixture.—H. A.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

The Composition of Chinese Red Glazes. H. Seger. Thonind. Zeit. 1891, 15, 853.

THE author having dealt with the general points in connexion with the preparation of Chinese red cuprous oxide glazes in a previous paper (Chem. Zeit. Rep. 1890, 14, 354 and 368), gives the composition of the glazes best suited for the so-called "Seger-porcelain," as follows:—

	Dark Red Glaze.	Light Red Glaze.	Blue Iridescent Glaze.
White porcelain glaze.....	75.00	70.00	70.00
Zettlitz kaolin	5.00	5.00
Oxide of copper	0.15	0.5—1.0	1.00
Oxide of tin	1.00	2.00	2.00
Oxide of iron	0.50	..	1.00
Baryta glaze.....	23.35	22.00	21.00
	100.00	100.00	100.00

Composition of the baryta glaze—
 $0.5 \text{ Na}_2\text{O}$ } $2.5 \text{ SiO}_2, 0.5 \text{ B}_2\text{O}_3$
 0.5 BaO }

In each case the heating of the mixture is effected in a reducing fire, and the product then ground up. The blue iridescent glaze becomes especially marked if the glaze is covered for a second time with the baryta glaze and then burnt. The most beautiful colours are obtained with other porcelain and earthenware glazes, when the difference in the melting point is very great, i.e., when the earthenware glaze is very fusible.—C. A. K.

The Composition of Sub-Glaze Colours for Soft Porcelain. H. Seger. Thonind. Zeit. 1891, 15, 891; and Chem. Zeit. Rep. 1891, 15, 347.

THE sub-glaze colours are produced by means of thick oil and turpentine, or of glycerol on burnt porcelain. After painting, and before putting on the final colourless glaze, the coloured porcelain must be heated to about the melting point of silver in order to drive out the oil or glycerol.

1. *Blue Colours.*—These are produced by cobalt oxide or phosphate; the latter gives clear transparent tones. 183 parts by weight of cobalt phosphate and 103 parts of commercial aluminium hydrate are ground together, dried, heated, again ground, and then washed with water. Lighter tints are got by using a larger proportion of alumina or by the addition of zinc oxide, but in this case the resulting colour is opaque. For *light blue*, 40.6 parts of pure zinc oxide, 69 parts of cobalt phosphate, and 103 parts of ignited alumina are used. A *very light blue*, closely resembling Turkish blue, results by employing a mixture of 71 parts of oxide of zinc, 17.2 parts of cobalt phosphate, and 103 parts of ignited alumina. For a *black-blue*, equal proportions of cobaltous and nickel oxides are used. The addition of chromic oxide gives green tints; for *dark blue-green*, 165.6 parts of cobalt oxide, 76.2 parts of chromic oxide, and 154.5 parts of ignited alumina are required. *Light blue-greens* are got by using either 40.6 parts of oxide of zinc, 56.4 parts of cobalt chromate, and 103 parts of ignited alumina, or 71 parts of zinc oxide, 14 parts of cobalt chromate, and 51.5 parts of ignited alumina. The cobalt chromate is prepared by the precipitation of 154.8 parts of anhydrous cobalt sulphate, by 97.1 parts of neutral potassium chromate; the precipitated chromate is washed, dried, and ignited.

2. *Green Colours*.—Nickel and chromic oxides are used. Nickel oxide alone gives *olive green*. 149.6 parts of nickel oxide and 76.2 parts of chromic oxide give a *dark green*. Pure chromic oxide give a *chrome-green*, and the so-called "Victoria Green" gives a bright green in a reducing fire.

3. *Red Colours*.—These are produced by means of gold, as already described by the author. (Chem. Zeit. Rep. 1891, 15, 281.)

4. *Black and Grey Colours*.—Chrome iron ore or an artificial ore prepared by heating 40 parts of ferrous oxide and 76.2 parts of chromic oxide in a reducing fire, is used. If the proportion of iron in the above mixture is doubled, a *brown-black* glaze results. By the addition of 20 parts of cobalt oxide to the mixture, a *blue-black* is obtained. *Grey colours* are got by diluting with porcelain mixture, or by adding 5 parts of iridium sesquioxide and 95 parts of porcelain mixture.

5. *Brown Colours*.—Both iron and manganese oxides are too readily dissolved by the glaze. The following mixtures gives the best results:—

Parts by Weight.	Dark Brown.	Red Brown.	Light Red Brown.	Yellow Brown.
Ferrie oxide	80.0	80.0	84.0	80.0
Chromic oxide	76.2	76.2	76.2	76.2
Enbith alumina	206.0	..	51.5	103.0
Zinc oxide	194.0	241.0	324.0

6. *Yellow Colours*.—Antimony is destroyed. The best yellow colours are got by using 141 parts of uranium oxide, and 150 parts marble, or 40 parts ignited rutile and 40.6 parts oxide of zinc.

All the above mixtures must be fired in the finishing oven for soft porcelain, as this aids the development of the colours. Also special attention should be paid to the thorough washing of the porcelain mixture. To make the colours more proof against the heat of the fire, they are ground up intimately, after being heated, with 33.3 per cent. of the porcelain mixture.—C. A. K.

Cuprous Oxide Sub-Glaze Colours for Soft Porcelain.

H. Seger. Thonind. Zeit. 1891, 15, 908.

Cupric oxide is not suitable for the production of sub-glaze colours on soft porcelain when an oxidising fire is employed, owing to its volatility which causes it to spread, but when a reducing fire is used this volatilisation does not occur. Instead of using pure cupric oxide the author recommends the following mixture which produces a red colour:—

	Parts by Weight.
Cupric oxide	7.5
Tin oxide	10.0
Barvta glaze $\left(\begin{smallmatrix} 0.75 \text{ Na}_2\text{O} \\ 0.75 \text{ BaO} \end{smallmatrix} \right) 2.5 \text{ SiO}_2, 0.75 \text{ B}_2\text{O}_3$	82.5

—C. A. K.

Composition of Glass suitable for Chemical Apparatus.

R. Weber. Zeits. f. angew. Chem. 1891, 662—665.

See under XXIII., page 267.

PATENTS.

Improvements in the Manufacture of Glass. T. C. J. Thomas, London. Eng. Pat. 4391, March 11, 1891.

The inventor formerly obtained a patent (Eng. Pat. 12,076 of 1886; this Journal, 1888, 35) for the use of oxygen in the manufacture of glass, the oxygen being blown through the molten metal and thus burning away carbonaceous matter and removing other impurities. The present invention consists

of an arrangement whereby the oxygen is collected and stored for use after being blown through the molten glass. The glass pot in which the "frit" is melted is provided with a cover furnished with two openings for the passage of the supply pipe and the outlet pipe. The outlet pipe passes to a gasoneter.—V. C.

Improvements in the Production of Glass-Making Material. W. Walker, London. Eng. Pat. 5324, March 25, 1891.

1x Eng. Pat. 2019 of 1891 (this Journal, 1891, 643) the inventor has described a process for the production of silicates for glass-making, by heating together sand, calcium chloride, and common salt. In the present process lime is substituted for calcium chloride when the latter cannot be readily or cheaply obtained.—V. C.

Improvements in the Method of and Apparatus for Manufacturing Glass Plates, Sheets, and Films. W. P. Thompson, Liverpool. From R. S. Pease, Minneapolis, U.S.A. Eng. Pat. 20,438, November 24, 1891.

This invention is a further extension of the principal of that described in Eng. Pat. 20,439 of 1891 (this Journal 1892, 163).

The plunger which serves as a "bait" to draw out a film or sheet of the molten or plastic glass when raised from the tank in which it had been dipped is in the improved process caused to form such a film or sheet, both during the upward and the downward stroke. For this purpose the bottom of the receptacle for the molten glass is furnished with gates. The metal backings of the gates are brought to a sharp edge where they bear against the plunger, making a close joint. When opened these edges serve as gauges to determine the thickness of the sheet or film. The thickness is further regulated and made uniform by rollers, between which, and the plunger, the adhering plastic glass is compressed. If desired the rollers may be used for figuring or marking the plates. When the sheets or films have been drawn downward to a sufficient distance the gates of the receptacle for molten glass are thrown upwards and against the plunger thus severing the sheets and preventing further escape of the molten glass.

The above process allows four films or sheets to be produced at a complete stroke of the plunger, two on the downward and two on the upward part of the stroke (see following abstract).—V. C.

Improvements in the Method of and Apparatus for Producing Cylinders, Pipes, and other Tubular or Hollow Bodies of Glass. W. P. Thompson, Liverpool. From R. S. Pease, Minneapolis, U.S.A. Eng. Pat. 20,440, November 24, 1891.

A "BAIT" of suitable form (see preceding abstract) is allowed to dip into a receptacle containing molten glass and provided with a raised central boss, of such dimensions that it is just covered by the "bait." While the "bait" is being drawn, air pressure is supplied through a tube or blowpipe communicating with the central boss, which is hollow. In this way the glass taken up by the "bait" is blown out to the required diameter. The diameter being once attained the air pressure is adjusted so as just to keep the body at this diameter.

The enlarging operation though not absolutely essential is highly desirable, since it enables a much smaller bait to be used and the drawing operation can be commenced under much more favourable conditions than would otherwise be the case.—V. C.

Process of Making Rose or Orange-Red Stained Glass. F. Welz, Klostergrab, Austria. Eng. Pat. 21,350, December 7, 1891.

ROSE-COLOURED glass is produced by adding selenium to the contents of the melting-pot, the depth of tint depending on the quantity of selenium used and also upon the ingredients of the glass, whether for hard or soft glass.

The orange-red colour is produced by mixing cadmium sulphide with the selenium before adding to the contents of the melting-pot, the amount of the yellow tint depending on the proportion of cadmium sulphide. In this process it is not necessary to re-heat the articles after being manufactured and to dip them in a colouring mixture, as in the ordinary process of making red glass.—V. C.

Improvements in Filtering Tubes with Ball Filtering Material for Purifying Molten Glass. M. Epstein, Berlin, Germany. Eng. Pat. 21,826, December 14, 1891.

This invention attains a *continuous* delivery of purified molten glass by the following device:—Into a melting-pot receiving the glass dips a tube with openings near the bottom. As the level of the molten glass in the melting-pot rises the glass flows in, and clay balls, till then resting on the bottom of the tube, are floated up on the surface of the molten glass till they reach a grid placed across the tube, against which they are retained in position by the upward flow of glass. As the level of the glass in the melting-pot rises the liquid passes by upward filtration through the interstices of the clay balls. As long as the level of liquid in the melting-pot is maintained sufficiently high, a supply of the filtered glass can be drawn off for use from the filtering tube. The number of working hours of the furnace is much increased by this invention, owing to its avoiding the necessity for re-charging, and the wear and tearing of plant is diminished.—V. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Influence of the Presence of Gypsum in the Raw Materials of Portland Cement. Erdmenger. Zeits. f. angew. Chem. 1891, 593—595.

GYPSUM is often used in the manufacture of Portland cement to retard the rate of setting, the addition of 0.5 to 2 per cent. to the finished cement sufficing for this purpose. Discretion is necessary in its use, as the addition of a comparatively small excess may lead to blowing and cracking. The same danger occurs when the gypsum is added to the raw materials instead of to the finished cement. It seems probable that much of the blowing may be due to the calcium oxide of the gypsum unduly increasing the total amount of lime in the cement. Should, however, the proper relation between the basic and acid constituents of the cement be maintained by increasing the proportion of clay, much larger quantities of gypsum may prove harmless. It must not, however, be forgotten that a portion of the lime will remain as calcium sulphide (which gives the cement a dark colour that deepens as the amount increases), from which calcium sulphate, with all its well-known tendencies to cause blowing, may afterwards form. One characteristic of cement made from raw materials containing gypsum is the tendency of the clinker to break up more readily than ordinary well-burnt cement. The following table shows the results of some experiments on the effect of

gypsum added both to the raw materials and to the finished cement:—

Percentage of Gypsum in Raw Material.	Tensile Strength (Kilos. per Sq. Cm. at 28 Days)	
	Without the Addition of Gypsum to the Finished Cement.	With 2 per Cent. of Gypsum added to the Finished Cement.
Nil	20.5	24.0
1.5	21.0	24.0
2.5	22.0	..
4	23.5	..
5	23.0	..
10	24.0	..
15	18.0	..

The age of the briquettes differed slightly in some instances from the normal period of 28 days, but not sufficiently to affect the value of the results. The tests were made in all cases on a mixture of 1 part of cement and 3 parts of sand by weight. A steady increase in strength occurred after the lapse of periods longer than that quoted. High and progressive results were also obtained with neat cement. Although the figures given in the original paper are thus favourable, it must be noted that the longest period of experiment was four months, save in the case of the cement containing an addition of 10 per cent. of gypsum, which at seven months showed a tendency to retrograde. Further experiments with cement made from a raw material containing an addition of 20 and 50 per cent. of gypsum showed that the product was unsound, and possessed a strong tendency to blow. The same raw material was used throughout, save that as the percentage of gypsum increased the quantity of lime was correspondingly diminished. The percentage of gypsum added is reckoned on the mixture ready for burning, and not on the quantity of cement to which it was added.—B. B.

PATENTS.

Method of Manufacturing Artificial Stones with Glass Surfaces. C. Breuer, Banzlau, Germany. Eng. Pat. 3532, February 26, 1891.

ARTIFICIAL stone with a glass surface is made by casting a concrete mixture upon the back of a sheet of glass placed face downwards in a mould with hinged sides. The back of the glass may be previously roughened and toughened, or coloured, etched, or otherwise decorated glass, in one sheet, or several pieces may be employed. Before the concrete is fully hardened, it may be grooved on the surface to aid the adhesion of mortar. The method is cheaper than that in which plate glass is attached to blocks of artificial stone as practised at present.—B. B.

Improvements in the Manufacture of Portland Cement. G. H. Skelsey, Hull. Eng. Pat. 3797, March 3, 1891.

THE patentee claims to manufacture Portland cement from hard chalk, such as is found in the neighbourhood of Hull, and usually considered valueless for this purpose, by grinding the chalk in an edge runner with specially constructed heavy runners, before it goes into the wash mill.

—B. B.

A New Manufacture of Materials suitable for Building, Paving, and other Purposes, from Waste Pieces or Debris of Slate. "The Société Anonyme des Ardoisiers de Deville" and V. V. der Heyden, Deville, France. Eng. Pat. 4750, March 27, 1891.

100 PARTS by weight of crushed slate are mixed with 7 parts of a mixture of equal parts of "colophonium" and tar or pitch, and the whole heated to 125° C. One half or one quarter per cent. of "olibanum" may be substituted for a similar amount of "colophonium," a portion of which may be replaced by Venice turpentine to modify the properties of the composition. 8 parts of lime, 4 parts of gelatin, and 1 or 2 parts of albumen may be used as the cementing material to add to 100 parts of the ground slate instead of the mixture described above. In this case the mixture is first made in the cold and then heated to 100° C. The composition may be moulded into blocks, slabs, or pipes, or used for making artificial slates, either alone or as a coating to wood, paper, or sheet metal. It may be used as a pavement after the addition of fine ballast; for this purpose the surface may be roughened or grooved. Ornamental effects may be produced by the incorporation of pigments. The material is said to be strong and water-proof. Joints can be made in it by simply heating the touching surfaces. The name patented for the material is "Ardoisine."—B. B.

Metallised Plates or Fabric of Asbestos or other Fibrous Material for Roofing and other Purposes. R. Graf, Westphalen, Vienna, Austria. Eng. Pat. 8831, May 25, 1891.

PLATES or fabrics made of asbestos or such like fibrous material are inconveniently porous and liable to disintegration. The remedy proposed by the patent consists in covering the asbestos plates or fabric with electrolytically deposited metal (copper or aluminium for instance), the article to be coated having first been rendered conductive by a film of graphite. Should the asbestos fabrics contain a cementing material such as glue, starch, or chloride of zinc, which is affected by free acids, the metal covering must be deposited from a neutral solution. The material to be coated may be manufactured so as to be waterproof by the following method: 50 parts by weight of fibrous asbestos are mixed with 10 parts of pounded asbestos felt waste, 10 parts of zinc oxide, and 300 to 500 parts of water; to which is added in succession, the mixture being constantly stirred, 7 parts by weight of zinc chloride solution (50° to 60° B), 10 parts of a solution of soap ("1 part by weight of best quality soap to 10 of water") 2 parts of a solution of alum ("3 parts by weight of alum to 21 of water"), 0.3 part of soda dissolved in 2 parts of water, and 0.8 part of lead acetate dissolved in 2 parts of water. The mixture thus prepared is moulded into plates, which are then metallised as described above.—B. B.

X.—METALLURGY.

Calorimetric Investigations of the state in which Silicon and Aluminium exist in Cast Iron. F. Osmond. Compt. Rend. 1891, 113, 474—476.

Silicon.—Troost and Hautfeuille (Compt. Rend. 81, 264) obtained the following results on dissolving silicides of iron in bichloride of mercury and measuring the quantity of heat liberated:—

Say 3,910 cal. per gram. of Silicon, and $3,910 - 760 = 3,150$ cal. for one gram. of silicon replacing one gram. of iron in the reaction.

	Heat liberated.		Difference.
	Found.	Calculated from Composition of Silicide.	
Silicide containing 3.5 per cent. Si and 0.6 per cent. C.	Calories. 970	Calories. 170	0
Silicide containing 7 per cent. Si and 0.4 per cent. C.	1,050	1,125	- 75
Silicide containing 12 per cent. Si and 0.4 per cent. C.	1,185	1,295	- 110
Silicide containing 14 per cent. Si and 0.4 per cent. C.	1,270	1,425	- 155

If the law indicated by these figures hold good for lower values than 3.5 per cent. of silicon, then it is obvious that silicon when present in very small proportion must be dissolved by iron with absorption of heat. The experimental verification of this inference has been undertaken by the author, who had at his disposal a series of samples obtained from R. A. Hadfield well suited for the purpose. The following table gives the analyses of the samples:—

Mark of Sample.	895 A.	898 D.	898 G.	898 I.	Ferro-silicon of Commerce.
Carbon	0.135	0.190	0.240	0.155	2.080
Silicon	0.200	2.100	4.100	7.340	11.720
Sulphur	0.074	0.060	0.042	..	0.020
Phosphorus	0.014	0.039	0.054	..	0.050
Manganese	0.110	0.150	0.200	0.270	4.320

The first three samples were forged and reheated; two others were not forgeable and were merely cast. The analyses and the calorimetric tests were made upon fine filings passed through a sieve of 80 meshes (to the centimetre?). The solvent used for the calorimetric tests was a saturated solution of the double chloride of copper and ammonia (500 cc. to each 1.5 gram. of metal). The results obtained were as follow:—

Mark of Sample.	898 A.	898 D.	898 G.	898 I.	Ferro-silicon.	
Heat liberated by 1 gram. of metal (a correction being made for carbon.)	Cal. 765	Cal. 843	Cal. 907	Cal. 926	..	
Excess of heat compared with sample 898 A.	found....	0	78	142	161	..
	calculated	0	60	123	225	..
Difference between "found" and "calculated."	0	+ 18	+ 19	- 64	..	
Time required for solution in minutes.	3	5	5	11	..	

In conformity with the inference drawn from Troost and Hautfeuille's experiments the difference between the quantities of heat found and calculated changes sign for a certain content of silicon.

The calculated amount of heat was arrived at from the formula—

The time required for the solution of the samples increases as the percentage of silicon in the samples increases. The sample of ferro-silicon containing 11.7 per cent. of silicon

was attacked with difficulty by the solvent, and after one hour a residue remained equal to 59 per cent. of the weight of sample taken, which was found to contain nearly the whole of the silicon present.

From these experiments it is evident that silicon can combine with iron with accompanying liberation of heat, but the compound formed is dissociated by an excess of iron and only exists when the silicon occurs to a sufficient degree in the alloy. Analogous examples are furnished by the solution of salts in water.

Aluminium.—The samples used were also obtained from R. A. Hadfield. They were treated in the same way as the samples of siliceous iron. The following was the composition of the samples:—

	898 A.	1167 A.	1167 G.	1167 L.
Carbon	0.140	0.150	0.210	0.220
Silicon	0.207	0.180	0.180	0.200
Sulphur	0.080	0.100	0.090	0.080
Phosphorus	0.050	0.040	0.030	0.030
Manganese	0.140	0.180	0.180	0.220
Aluminium	0.000	0.210	2.100	6.200

The following calorimetric results were obtained:—

	Cal.	Cal.	Cal.	Cal.
Heat liberated by 1 grm. of metal (a correction being made for silica and carbon)	751	779	883	1,054
Excess of heat compared with 898 A.	0	19	132	303
Excess of heat compared with 898 A.	0	10	113	293
Difference between "found" and "calculated"	0	+ 9	+ 19	+ 10

The calculated excess of heat was arrived at from the reaction—

$$- 6 \times 62,600 + 475,600 + 6 \times 33,340 = 300,040 \text{ cal.}$$

say 5,480 cal. for 1 grm. of Al, (=27.4) and 5,480—760 = 4,720 cal. for 1 grm. of Al, replacing 1 grm. of Fe in the reaction.

The above results show that the discrepancy between the amounts of heat found and calculated is in each case small, and the relative difference becomes of less importance the higher the percentage of aluminium in the sample. But this difference is always of the same sign. Moreover all the samples, up to 10 per cent. of aluminium (which was the alloy richest in aluminium that was used in these experiments) dissolved with equal rapidity in the solution of the double chloride of copper and ammonium.

It follows, therefore, that aluminium under the conditions in which it is used in the metallurgy of iron, dissolves in cast iron with absorption of heat. If then, as practical men affirm, a liberation of heat actually takes place, this cannot be ascribed to an exothermic combination of the two metals, but must be due to the reduction by the aluminium of the dissolved oxide of iron, and probably also to the formation of an allotropic modification of the iron. That modification which is produced normally at about 850° when iron is cooling, is found not to take place in the presence of a sufficient quantity of aluminium, and consequently the modification should occur at the moment of adding the aluminium.—H. S. P.

Volatility of Nickel in Presence of Hydrochloric Acid.

P. Schützenberger. *Compt. Rend.* 1891, **113**, 177—179.
HYDROCHLORIC acid gas would seem to play a part analogous to the part played by carbon monoxide in its action on nickel. If pure chloride of nickel, previously sublimed in a current of nitrogen, be reduced in dry

hydrogen, a volatile product is obtained containing nickel, as may be shown by heating the after part of the reduction tube to dull redness, when a deposit of nickel chloride is obtained. To ascertain whether this was to be accounted for by some of the chloride being mechanically conveyed away by the hydrochloric acid formed during reduction, the hard-glass reduction tube was half-filled with the anhydrous chloride, after which came a long layer of closely packed glass wool. To the end of the reduction tube was then attached a narrow glass coil, giving a path of four metres to the gases escaping from the reduction tube; from this coil the gases passed through a straight glass tube, entering through a wad of glass wool. Nickel chloride carried mechanically from the reduction tube could not possibly reach the second straight tube with such an arrangement, and no condensation whatever was noticeable in the coil, which was kept at the prevailing atmospheric temperature; yet on heating the second straight tube to redness a deposit of nickel chloride was obtained. Analogous results are obtained on passing dry hydrochloric acid gas over finely-divided nickel. The true composition of the volatile compound has not yet been ascertained, though the author seems inclined to consider it a hydrochloride of nickel.

Iron and zinc give a similar reaction. (Compare this *Journal*, 1890, 808; 1891, 644 and 836.)—T. L. B.

On the Volatilisation of Iron and Nickel by Carbonic Oxide. J. Garnier. *Compt. Rend.* 1891, **113**, 189—191.

IN connexion with recent publications concerning volatile carbonic oxide compounds of metals (see this *Journal*, 1890, 808; 1891, 644 and 836, and preceding abstract), the author makes the following observations:—

The gases escaping from a charcoal blast furnace in normal action give a perfectly blue flame on burning, but if the temperature of the furnace be allowed to fall somewhat, the escaping gases form a thick smoke and burn with a white flame, ferruginous matter being deposited. The explanation would seem to be, according to the recent observations of Berthelot, that carbonyl compounds are formed and evolved at the lower temperature which cannot exist at the higher temperature. As the cooling of such furnaces sometimes causes a deposit of zinc, the whitening of the flame has been attributed to zinc, but this could not be the case in the furnaces at which the present observations were made. Further, the instance of manufacturing iron-nickel alloys is quoted, where nickel and cast iron are melted together in plumbago crucibles; on removal from the furnace an immense shower of sparks escapes, which, it is suggested, may be due to volatile carbonyl compounds.—T. L. B.

Behaviour of Hydrogen towards Lead and other Metals. G. Neumann and F. Streintz. *Monatsh.* 1891, **12**, 642—660.

See under XI., page 247.

The "Ore Process" in the Basic Open-Hearth Furnace. Dr. Leo. Dingl. *Polyt. J.* **282**, 13—17, 41—45, and 81—85.

AFTER a historical review of the development of processes of steel manufacture in open-hearth furnaces, the author describes the experiments made by M. L. Imperatori on the further substitution of ore for scrap in the modern process.

The method adopted as a result of these experiments was to mix finely-powdered ore with just sufficient powdered coke to reduce it to metal without carburising it, damp the whole, shape it into briquettes or blocks by hydraulic pressure, thoroughly dry, and smelt. The ore used should be roasted free from carbonic anhydride and water and should not contain less than 50 per cent. of iron; it should be as free as possible from silica and lime; sufficient lime may however be introduced to form a mono- or bi-silicate with any silica present. About 22—25 per cent. of powdered coke

or 26—35 per cent. of coal are required for rich Elba ore. The blocks weigh about 20—30 kilos. each; they are air-dried under cover for 7 to 8 days, then brought near the furnaces and thoroughly dried; they acquire a certain solidity from the conversion of a portion of the sesquioxide of iron in the ore into the hydrated oxide $\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ which acts as a cement. These blocks are not generally smelted alone; they may be introduced into an iron bath in a Siemens furnace, or mixed charges of pig iron, blocks and scrap may be worked. In the latter case the pig iron is first charged in, a layer of blocks is then added, and the whole is covered with scrap; the charge melts in about an hour, when quantities of 30—40 blocks are repeatedly introduced at intervals of 12—15 minutes. When the bath is at work it is covered with a slag which is black at first, but gradually turns a light green, and contains very little iron. It is rarely necessary to add ore to the bath to soften the metal, this result being attained by adjusting the composition of the blocks so that no carburised iron is produced and a slight excess of oxide is available for the decarburisation of the bath. The decarburised metal is so hot that the end of an iron pole thrust into it is melted in a few seconds, and, on adding ferrosilicon and ferromanganese to the bath, the resulting steel may at once be tapped.

In working open-hearth furnaces in the usual manner the experimenter's ordinary charges consisted of about 30 per cent. of flawed ingots, rail-ends, scale, &c., from the preceding charge, about 35—40 per cent. of pig iron, and 30—35 per cent. of other matters, chiefly scrap. The first experiment with ore blocks was made with the object of substituting them for this 30—35 per cent. of scrap. 1,050 kilos. of ore (from Elba), 380 kilos. of powdered coal, and 25 kilos. of lime in the form of milk of lime were well incorporated, consolidated with heavy stamps into 62 blocks, dried for 10 days in the air and for 24 hours near the furnace. 800 kilos. of grey Bilbao pig iron were now charged into the furnace, and on this the 62 blocks were placed; the charging occupied 20 minutes, and only one of the blocks broke up during the operation. In an hour the blocks became spongy, and in 1½ hours from the commencement of the charging 800 kilos. of steel scrap were placed on the half-molten sponge; one hour later, a sample taken consisted of a fine-grained steel; the slag was glassy, light green in colour, and contained prills of soft metal; three hours after charging, 50 kilos. of ore were thrown into the centre of the bath, the temperature being sufficiently high, and 20 minutes later 30 kilos. more were added; 10 minutes afterwards the metal was soft. 3 hours 49 minutes after charging, 25 kilos. of ferrosilicon with 14 per cent. of silicon and 25 kilos. of ferromanganese containing 40 per cent. of Mn were thrown in; five minutes later 30 kilos. of ferromanganese with 72 per cent. of Mn were added and the charge tapped. The product consisted of five flawless ingots weighing 407 kilos. each and 81 kilos. of scrap, &c., thus affording a yield of 557 kilos. of iron for the 1,100 kilos. of ore. The composition of the metal was: Carbon 0.252 per cent., silicon, 0.250 per cent., phosphorus 0.060 per cent., sulphur 0.100 per cent., manganese 1.090 per cent. The product was tough and could be rolled with facility. Test pieces of rails made from this metal, weighing 36 kilos. per metre and placed on supports 1.10 metres apart, were uninjured after receiving three blows from a ram of 600 kilos. weight falling from a height of 8 metres, the test pieces being three times bent back at the point of impact. A test piece, 160 mm. long and 16 mm. diameter, had a breaking strength of 56 kilos. per square millimetre, an elongation of 20.10 per cent., and a diminution of sectional area of 41 per cent.

The high percentage of sulphur was principally due to the coal used, and could have been reduced by weathering the blocks for a longer time, the sulphur under these conditions being oxidised to sulphate, which is decomposed in the furnace. When working on an acid hearth, weathering the blocks affords the only means of eliminating the sulphur.

In another experiment an attempt was made to render the blocks more compact by substituting coke for coal, so that the whole charge of blocks might be introduced at once into the furnace. An excess of coke (28.2 per cent.) was

however used with the result of making the mass very infusible, prolonging the operation for 10 hours, and necessitating the addition of a considerable quantity of spiegeleisen to promote fusion. The introduction of the whole charge of blocks at once also proved prejudicial. The yield was however, very good (56.1 per cent. of the ore), and the product was a good quality of ingot iron. The slag was very acid and poor in iron. In view of the refractory character of blocks prepared with coke, a number of trials was made with single blocks, and from these it appeared that by decreasing the amount of coke added, and substituting a little dolomite for the lime, the time of reduction could be reduced by one-half and a readily fusible slag obtained. This depends on the formation by the excess of oxide of a fusible silicate of iron $3\text{FeO} \cdot \text{SiO}_2$ which combines with magnesia, forming a very fusible double silicate, which is subsequently reduced by the carbon in the pig iron.

For the next charge a batch of 120 blocks were accordingly compounded of 2,625 kilos. of powdered ore, 551 kilos. (21 per cent.) of powdered coke, 131 kilos. (5 per cent.) of dolomite, and 10 per cent. of water. Five tons of Bilbao pig iron were charged into the furnace, then 4 tons of small scrap; this operation occupied two hours. In 3 hours 20 minutes from the commencement the metal was incompletely fused; the blocks were now added in small quantities at intervals of 10—15 minutes; 3 hours 10 minutes later the bath was completely fused, and a sample taken out consisted of a hard high-carbon steel. 7 hours 30 minutes after starting, 230 kilos. of lump ore were added in portions, and a sample taken out was found to be completely decarburised. One hour later, 70 kilos. of ferrosilicon containing 11 per cent. of silicon and 100 kilos. of ferromanganese with 40 per cent. of manganese were added; the metal was not however tapped till half an hour later, in consequence of an accident; it was then a homogeneous ingot iron, almost too soft for rails. The composition was: Carbon 0.17 per cent., silicon 0.095 per cent., phosphorus 0.1013 per cent., sulphur 0.074 per cent., manganese 0.531 per cent. The yield from the 2,855 kilos. ore introduced was 1,635 kilos. of iron (57.2 per cent.)

The preceding experiments were all conducted in an acid-lined furnace, but experiments are in progress on the smelting of ore blocks on the basic hearth. Ores poor in silica may be expected to yield good results and a product free from sulphur and phosphorus. Five per cent. of lime in fragments is mixed with the ore to eliminate the sulphur, but the addition of milk of lime or other substances which might prevent the intimate contact of the ore and fuel must be avoided. Phosphorus is gradually removed from the bath during the oxidation period when the bath is being decarburised. It is preferable to substitute well-washed powdered caking coal for coke, and a high pressure should be used in consolidating the blocks; the temperature of the furnace should be rather high, so that the reduction (of the Elba ore) occurs according to the equation—

the slag should be periodically removed to prevent re-absorption of the sulphur.

The Imperatori process appears to require a larger consumption of fuel than the ordinary process, but the amount of this excess has not been clearly ascertained.

The remainder of the paper is taken up with an account of the basic open-hearth process as practised in England, and with a description of the Hilton-Eston modification of the Batho furnace.—S. B. A. A.

On the Durability of Aluminium. C. Winkler. Zeits. f. angew. Chem. 1892, 69.

THE author published results a number of years ago (Deutsche Industriezeit. 1877, 64) showing that with continuous use the losses in three spoons of different composition were as follows:—

	Per Cent. per Year.
Silver spoon	0.403
Aluminium spoon	0.630
German silver spoon	1.006

The silver and aluminium spoons have been in daily use now for 16 years; the third spoon, however, has not been used with the same regularity. The loss during the 16 years has amounted in the case of the silver spoon to 8.78 per cent., a result rendered too high by continual polishing; the aluminium spoon has lost 5.85 per cent., a result which may be taken as correct, since this spoon has been rubbed merely with a soapy flannel as attempts at polishing were useless; lastly, the loss in the case of the third spoon has amounted to 5.62 per cent., a result decidedly low, seeing that this spoon has not been regularly used.

It thus seems evident that, as regards durability, there is not very much to choose between silver and aluminium, whilst German silver wears away more easily than either. Hence Lübbert and Roscher's statement (see *Zeits. f. angew. Chem.* 1892, 7) is assumed to be without foundation.

—T. L. B.

Direct Production of Iron and other Metals from their Ores. N. Lebedieff. Swed. priv. 1890, 16 and 20; *Chem. Zeit. Rep.* 1891, 15, 350.

THE process consists in combining the oxides of the metals with strong bases either by fusing the finely-ground ore with potash, soda, limestone, dolomite, &c., or, as in the case of chromium and of manganese by roasting a mixture of the ore and the above bases in a furnace, with access of air, the mass being repeatedly well mixed during the operation. The addition of sodium chloride or of saltpetre aids the process. Also some compounds of the metallic oxides with alkalis, such as the aluminates, can be prepared by a wet method. The fusion can be carried on either in blast furnaces, open hearths, or reverberatory furnaces. The charge consists of ore mixed with basic oxides as stated, to which mixture wood-charcoal or coke and sufficient siliceous material to form a slag with the resulting metal, are added. To prevent the furnaces from being attacked they should be lined with some neutral material. For the reduction of iron and other easily reducible metals the coke may be replaced by reducing gases such as carbon monoxide, hydrogen or hydrocarbons. In this case the fusion is conducted in reverberatory furnaces heated either in the usual way or by regenerative fires, into which the gases are led by pipes which pass to a certain depth in the fused mass; or else the pipes pass into the furnace through the side walls and are connected on the other hand with high-pressure generators or gasometers. As the fusion proceeds and the metal separates, small quantities of the ore mixed with the basic oxides are added from time to time so as to form a thin covering over the molten mass. In cases where the metallic oxides will combine with the basic oxides by direct fusion, the preparation of the ore and the fusion can be carried on in one and the same furnace. Readily fusible metals are tapped as they separate, whilst the more difficultly fusible, such as iron and chromium, are removed from the furnace when a sufficient quantity has accumulated and separated from the alkaline salts by treatment with water or acids after cooling, when the metal remains behind in the form of small plates. Another method is to add to the reduced mass some substance which will lower the melting point of the metal and thus allow of its being tapped; for instance this may be effected in the case of iron by the addition of cast iron rich in carbon.—C. A. K.

Conversion of Cast Iron into Wrought Iron and Steel. N. Lebedieff. Swed. priv. 1891, 18; *Chem. Zeit. Rep.* 1891, 15, 350.

THE author employs the above method of working (see previous abstract) for the conversion of cast iron into wrought iron and steel and for the purification of other metals from impurities such as carbon, sulphur and silicon. To effect this the compound of the metallic oxide with a strong base is fused in a reverberatory furnace and the cast iron then added to the fused mass. The latter melts and under the influence of the basic oxides the carbon, sulphur and silicon are oxidised, whilst the metal originally added as oxide separates in the free state. Small quantities of the

ore are added from time to time as the process proceeds; stirring aids the reduction. The choice of the basic oxides depends upon whether the pure metal or an alloy is required. In the former case a compound of ferric oxide and a basic oxide is mixed with the cast iron; whilst in the preparation of wrought iron or of steel containing chromium, manganese or aluminium, the oxides of these metals are employed in addition.—C. A. K.

On Certain Ternary Alloys. Part III., C. R. Alder Wright and C. Thompson; Part IV., C. R. Alder Wright, C. Thompson, and J. T. Leon; Part V., C. R. Alder Wright. *Proc. Roy. Soc.* 49, 156, 174; 50, 372.

THE experiments described in these three papers are in continuation of those previously abstracted (*this Journal*, 1890, 944). The later results are expressed in accordance with a system of graphical representation proposed by Sir G. G. Stokes in a note embodied in Part IV., in which the composition of a given mixture of three substances is expressed by the position of the centre of gravity of three weights placed respectively at the three corners of an equilateral triangle, and representing the relative masses of the three constituents. With certain pairs of metals, e.g., lead and zinc, each will only dissolve the other to a limited extent when molten, so that a mixture of the two (outside of certain proportions) separates into two binary alloys, one containing mainly lead with a little zinc, the other chiefly zinc with a little lead, the exact proportions varying slightly with the temperature. If the weight representing the heavier metal, lead, be placed at the left of the base of the triangle, and that representing the lighter one, zinc, at the right, the compositions of these two alloys are respectively indicated by two points situated on the base line not far from the two corners respectively. If a third metal, e.g., tin, be added to the mixture, such that this third, or "solvent" metal will mix in all proportions with either of the other "immiscible" metals separately, the composition of the entire mass is indicated by a point within the triangle raised above the base to an extent proportionate to the amount of tin added (the weight representing tin being placed at the apex of the triangle), and inclining to the left hand side or to the right according as lead predominates over zinc, or *vice versa*. The mixture thus formed is a "real" alloy if it remains uniform in composition when well intermixed and allowed to stand molten for some time; but in many instances this is not the case, the mixture separating into two different ternary alloys, a heavier one where lead predominates, whilst some tin and a little zinc are present, and a lighter one mainly consisting of zinc but also containing some lead and tin. The points indicating these two alloys consequently lie respectively to the left and right of the point representing the entire mass, or "ideal" alloy employed. The line joining them is termed a "tie line" or "tie;" necessarily, the point indicating the "ideal" alloy used is situated on this line nearer to the one or the other of the "conjugate points," according as one or the other alloy is formed in larger quantity. By employing a series of mixtures with the "solvent" in gradually increasing proportions, two branches of a "critical curve" are traced out by the positions of the left-hand and right-hand members of the various pairs of conjugate points deduced. These two branches tend to run one into the other, meeting at a point termed the "limiting point" where the system of tie lines ultimately vanishes. The critical curve thus indicates the boundary between "real" and "ideal" alloys; all points lying inside the space included between the base of the triangle and the critical curve correspond with ideal alloys, whilst all points inside the triangle but outside the critical curve correspond with real alloys. If the tie lines slope downward to the left, the "solvent" is contained in larger proportions in the heavier alloy than in the lighter one, and *vice versa* if they slope downward to the right.

A number of the earlier experiments appeared to indicate that the positions of any two conjugate points (with respect to the point representing a given ideal alloy from which the two alloys indicated by these points are formed) are to a

slight extent variable with the relative proportions in which the heavier and lighter immiscible metals are contained in the ideal alloy used. This matter has been carefully investigated, with the result of demonstrating that the apparent variation is simply due to the great difficulty experienced in obtaining a sufficiently thorough and complete intermixture of metals melted in a crucible. The error introduced is sensibly least when the two ternary alloys formed are produced in approximately equal volumes, or at any rate when the heavier one does not predominate, which would render thorough intermixture more difficult. By substituting for molten metals substances fluid at the ordinary temperature (more especially mixtures of chloroform and water as "immiscible" substances, with glacial acetic acid as "solvent"), it was found that *absolutely invariable conjugate points* were obtainable with all proportions of materials forming mixtures representing different points on a given tie line, when thorough intermixture was brought about by shaking vigorously for some time in a stoppered bottle. A critical curve was thus traced out for water, chloroform, and acetic acid, such that the ties uniformly sloped downwards to the left (chloroform). The position of the limiting point was not the point of the curve reaching the greatest elevation above the base, but was situated *lower down on the left-hand side*; at this point the ratio of water to chloroform was sharply that indicated by the formula $2\text{C}(\text{HCl}_3, 5\text{H}_2\text{O})$. "Ideal" mixtures situated anywhere near this point were found to be excessively sensitive to temperature variation, a difference of a few tenths of a degree making a wide difference in the composition of the two ternary mixtures formed, and in some cases making all the difference as to whether the mixture remained an "ideal" one, or became "real"; in all cases the effect of temperature variations was such as to be included in the general rule, *the critical curve for a higher temperature lies inside that for a lower one*.

Exactly the same peculiarities (*mutatis mutandis*) are found to characterise the curves obtainable with suitable metallic mixtures; the same rule as to effect of temperature variation always applies, so that the sensitiveness of the mixture to temperature is very considerable for ideal alloys near the critical point, although towards the base of the curve comparatively little effect is producible, even by a difference of 50° or 100° . Certain differences, however, are noticeable with particular metallic mixtures, as regards the general characters of the critical curves and tie lines; with some ternary alloys the ties always slope to the left (e.g. lead—zinc—silver and bismuth—zinc—silver); with others, always to the right (e.g. bismuth—zinc—tin); with two (and two only, out of a dozen under examination, viz. lead—zinc—tin and lead—aluminium—tin) the lower ties slope in one direction (to the left) and the upper ones in the opposite direction; this appears to be due to the existence of a tendency towards the formation of definite atomic compounds, on the one hand of tin and lead, SnPb_3 , on the other of tin and zinc, or tin and aluminium, respectively SnAl_3 and SnZn_4 . With most ternary mixtures no marked irregularity in the contour of the critical curve is noticeable, but in some cases notable exceptions to the rule exist; thus alloys of lead—zinc—silver, and bismuth—zinc—silver exhibit remarkable bulges (inwards and outwards) in both branches of the critical curve, the situation of which, and the positions of maximum bulge, lead to the deduction that two definite compounds of zinc and silver exist, respectively Ag_2Zn_3 and Ag_4Zn_5 . No such bulges, however, are noticed in the corresponding alloys where aluminium replaces zinc.

In any given curve containing lead as one of the two immiscible metals, substitution of bismuth for lead invariably depresses the critical curve, *ceteris paribus*; so that the bismuth-containing alloys furnish critical curves lying *inside* the respective analogous curves obtained with lead-containing alloys. Precisely the opposite effect appears to be produced by the substitution of aluminium for zinc.

The exact positions of the various limiting points, it was found, could not be arrived at by direct experiment on account of the sensitiveness to temperature variation near these points, and because the two alloys formed differed but little in density, and therefore did not readily separate from one another. Close approximations, however, were deducible

by means of two graphical methods suggested by Sir G. G. Stokes. The limiting points thus deduced never coincided with the point in the critical curve where the elevation above the base line was a maximum, but always lay more or less lower down, on one side or the other, on the left-hand side; when the upper ties sloped downwards to the left (e.g., lead—zinc—silver, bismuth—zinc—silver, chloroform—acetic acid—water), on the right-hand side if they sloped downwards to the right (e.g., lead—zinc—tin, bismuth—zinc—tin). The two immiscible metals were present at the limiting points in ratios close to those indicated by definite atomic formulae; but the formulae varied according to the nature of the solvent metal, being wholly different with tin as compared with silver, thus—

With lead—zinc—tin alloys the ratio was near..... PbZn_2

With lead—zinc—silver alloys the ratio was near... Pb_2Zn

With bismuth—zinc—tin alloys the ratio was near... BiZn_{10}

With bismuth—zinc—silver alloys the ratio was near BiZn_2

Full details of the methods of investigation and analysis employed are given in the papers, together with numerous tables of values obtained and plottings of the critical curves and tie lines thence deduced.—C. R. A. W.

The Baltimore Meeting of the American Institute of Mining Engineers, February 16—20, 1892. Eng. and Mining J. 1892, 227—229.

THE COPPER MINES OF VERMONT: II. M. HOWE.

THE ancient slates of the Appalachian range contain a series of large beds of iron pyrites extending from Alabama to the St. Lawrence. These deposits occur in the form of enormous lenses, and though they have many of the characteristics of fissure veins, are not generally thought to be such, but to be true ore beds, their irregularities being due to folding and distortion during metamorphism. In the majority of cases, although there are marked exceptions, these lenses pinch out in depth. In the Southern States the upper part of the ore body has been decomposed and the copper leached out. Below the gossan is found a rich layer of copper ore, resulting, perhaps, from the reprecipitation of the leached copper. Below this again is the region of undecomposed sulphides, which become impoverished as depth increases.

In the Northern States both the gossan and richer portion are eroded, leaving the undecomposed sulphides exposed at the surface. The sulphides continue in depth without loss of their percentage of copper, and in some cases are said to have been enriched. In the Elizabeth mine the ore has been worked down on the pitch for 1,500 ft., and in places some 60 ft. in width. At the Union mine, while the ore body does not extend continuously to a great depth, yet continuations of new lenses are found by cross-cutting when the lense pinches.

Although at present the pyrrhotite ores are placed at a disadvantage with the pyritous ores, as far as utilisation for acid-making is concerned, they contain a larger proportion of copper, and when the gigantic sulphur beds of Louisiana are developed they will be on a par, at least, with the pyritous ores.

THE MAGNETIC ORES OF ASHE COUNTY, N. C.:

H. B. C. NITZE.

These iron ore deposits, situated in an area of crystalline rocks and embracing an extent of 150 square miles, are practically undeveloped, though some small prospecting has been carried on, and one small Catalan forge, making a very superior tough iron, is in operation. The ores are principally magnetites, suitable for the manufacture of Bessemer pig iron, though hematites and red specular ores of excellent quality are also found, but in very limited quantities. Mr. Nitze divides Ashe County into three main belts—the Ballou or River belt, the Red Hill or Poison Branch belt, and the Titaniferous belt.

The Ballou belt has been opened at several points, showing thick beds of ore material running from 41·36 per

cent. metallic iron to 60·48 per cent., and extremely low in phosphorus and sulphur, but high in silica. The Red Hill or Poison Branch belt has been opened at numerous points along its outcrop, showing large bodies of ore. In addition, the bodies have been traced over unopened ground by the dipping needle. The ore generally is good in character, although certain portions are high in sulphur. The Titaniferous belt is extensive and persistent, and shows large quantities of ore, but the percentage of titanate acid from 8·8 per cent. to 9·7 per cent. condemns it for blast furnace use.

TITANIFEROUS IRON IN THE BLAST FURNACE.

R. W. Raymond suggested that for the benefit of iron workers the boundaries of the titaniferous ores, which seem to run in a belt from the large developments in the South, through New Jersey, New York, and into Canada itself, should be determined. Raymond stated that the Durham furnace had been paying a rental for 20 years on a magnificent body of iron ore which was absolutely useless to it on account of its high percentage of titanate acid, although it was extremely low in phosphorus. The titanate acid ran as high as 14 per cent. It was well known to metallurgists, he said, that titaniferous ores could be treated in the blast furnace by carrying large quantities of alumina in the slag; but at Durham, where they relied upon the Trenton dolomite as a flux, the alumina was not obtainable. Many of the metallurgists of the Lehigh Valley had found accretions of nitro-cyanide of titanium in their furnaces, showing that where titanate acid occurred in small quantities it was accumulative. In the late T. Sterry Hunt's classification of crystalline rocks the titaniferous ores had been placed as characteristic of a certain era, and although this hypothesis has not been proved conclusively, it was in his (Raymond's) opinion most likely to be correct. The aluminous and titaniferous slags, Dr. Raymond said in reply to a question, ran poorly and were difficultly fusible. They were sometimes used to "heal" a damaged hearth.

President John Birkinbine stated that the titaniferous iron deposits of Northern New York and Canada were bounded on either side by bodies free from that element. Titaniferous bodies, strange to say, were placed in the most inviting of positions; huge outcrops enticed the miner. It was Birkinbine's opinion that the salvation of the titanium difficulty lay in the use of large hearths removable while in blast if necessary. This has been done on a small scale, he said, and why not on a large one.

Dr. Raymond thought the remedy, if any, would be the employment of some of the modern direct open-hearth processes. Howe, however, coincided with Birkinbine. Birkinbine continued by saying that magnetic concentration reduced materially the amount of titanate acid in the product. Dr. Eggleston said that this was true, but that he had made a number of experiments, which showed plain jiggling would effect the separation of certain titaniferous minerals from magnetite.

Improvements in the Manufacture of Galvanised Iron.

J. W. Richards. Eng. and Mining J. 52, 24, 1891, 677.

The author has found that the presence of small quantities of aluminium in the galvanising bath leads to the deposition of a highly crystalline as well as a permanently brilliant and adhesive coating of zinc. The aluminium is best added to the bath in the form of a zinc alloy containing 2 per cent. of aluminium, 4 oz. of this alloy being added to the galvanising bath for every ton of zinc.

Calculation of Slag Components.

G. Murray. Eng. and Mining J. 1892, 281.

See under XXIII., page 270.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

Behaviour of Hydrogen towards Lead and other Metals.
G. Neumann and F. Streintz. Monatsh. 1891, 12, 642—660.

In order to explain some physical phenomena which take place at the negative plate of a secondary battery, it was assumed in a previous paper that lead has the power of absorbing hydrogen; the authors attempted to put this assumption to the test of experiment under conditions similar to those existing in a secondary battery, but no trustworthy conclusions could be drawn from the results.

They then examined the behaviour of molten lead, and found that it has the power of absorbing 0·11—0·15 vol. of hydrogen. Several other metals were examined as regards their power of occluding hydrogen, and the results are given in a table.—F. S. K.

Determination of Electrolytic Dissociation of Salts by Solubility Experiments.

A. A. Noyes. Technology Quarterly, 1891, 4, 259—291.

THE effect which one salt exerts on the solubility of another has been the subject of numerous investigations. These, however, yielded nothing more than a mass of empirical results, until Nernst showed that the electrolytic dissociation theory offered an explanation of this phenomenon of solutions. The author has already (Zeits. f. Phys. Chem. 6, 241) tested by experiment the validity of Nernst's theory, and has generally found it to hold good. Such discrepancies as did occur were probably due to the incorrectness of the dissociation values used in the calculations, i.e., to the assumption that dissociation and molecular conductivity are proportional. Now, just as the solubility of one salt in presence of another can be calculated if the values of the dissociation be known, so conversely can the degree of dissociation be determined from the values of the solubility experimentally obtained. Up to the present time electric conductivity is the only physical property of a solution which has been used to furnish a measure of the dissociation of the substances dissolved in it. Although this method, as used by Ostwald and others, gives reliable results in the case of organic acids, the author believes that it cannot be depended on in the case of better conductors, such as most metallic salts and strong acids and bases. These considerations have led the author to study the dissociation of the chlorides of various metals by methods depending on their solubility. He arrives at the following general results.

The effect of 11 different chlorides on the solubility of thallous chloride was investigated, each in four distinct concentrations, and the dissociation of each was calculated from the solubility effect. The three alkali-metal chlorides, potassium, sodium, and ammonium, were found to be equally dissociated, their dissociation increasing from 65 per cent. in the case of a solution of 0·2 normal strength to 89 per cent. at 0·03 normal. The dissociation of hydrochloric acid was slightly greater (73 per cent. to 89 per cent.). With a single exception all the bivalent-metal chlorides investigated (Mn, Ca, Ba, Zn, Mg, and Cu) proved, like the univalent-metal chlorides, to be equally dissociated. Their dissociation is about 5 per cent. less than that of the alkali chlorides. Cadmium chloride forms the exception spoken of, its dissociation being 33, 43, 53, and 60 per cent., as against 62, 69, 78, and 82 in the case of solutions of the other chlorides of corresponding concentration. The results were confirmed by corresponding experiments with lead chloride.—D. E. J.

PATENTS.

Manufacture of Porous or Spongy Plates, applicable for Use in Secondary Batteries, &c. F. T. Williams and J. C. Howell, Llanelly. Eng. Pat. 2573, May 23, 1883. (Second Edition.)

This invention relates to the formation of porous blocks of lead or its alloys by removing in a perforated kalle, such as

is used in the separation of lead and silver, some of the molten metal which has been allowed to cool slowly until it is just crystallising out. The liquid metal drains through the perforations, and the mass which remains sets into a porous block, which can be cut up into battery plates or be used for the manufacture of white lead.—G. H. R.

Improvements in Extracting Precious Metals from Ores or Minerals containing them, and Apparatus therefor. J. B. Hannay, Dumbarton. Eng. Pat. 11,966, September 22, 1890.

In Eng. Pat. 14,061 of 1886 (this Journal, 1887, 673) a process is described for extracting gold from refractory ores by the combined action of chlorine, a cyanide, and electric currents. In the present patent, chlorine is dispensed with, the electrolyte being kept in a state of circulatory agitation by means of a screw or propeller. Gold or silver ores are reduced to a fine powder and mixed to the consistency of a fluent sludge with water containing not more than 2 per cent. of potassium cyanide.

Apparatus is illustrated and described for effectively carrying this method into effect (see below, Eng. Pat. 19,181 of 1890).—E. T.

An Improved Process and Apparatus for Extracting Gold from Minerals containing it. J. B. Hannay, Dumbarton. Eng. Pat. 19,181, November 25, 1890.

This patent is for an improvement in apparatus for effecting the process described in Eng. Pat. 11,966 of 1890 (abstracted above). The negative electrode is of mercury, immediately under a propeller mounted on a vertical shaft passing through the bottom. The positive electrode is a hollow inverted cone of carbon mounted immediately over the propeller. By the action of the latter, the sludge is drawn through the hole in the cone and driven up round the sides to once more enter the hole at the top and continue the circulation.—E. T.

A New or Improved Dry Couple or Element for Electrical Purposes. H. Birkbeck, London. From O. Genrichsen, Copenhagen, Denmark. Eng. Pat. 20,838, December 20, 1890.

In this cell, the carbon is placed in the centre, with its lower half surrounded by a mixture of pyrolusite and graphite. Between this layer and the zinc, which is in the shape of a cylinder surrounding the whole, is the solution of sal-ammoniac, of which the absorbent material is siliceous marl. There is then a thin horizontal layer of siliceous marl, made firmer by the addition of plaster of Paris. Above this there is a very deep layer of sawdust or such material. The cell is closed at the top by layers of plaster of Paris and asphalt or resin. A hole is left through the two top layers, and, if desired, a long bent tube may be attached to it, so that any gases liberated must pass through a great length of absorbent material contained in it, the tube itself being wholly contained in the cell.

—E. T.

Improvements in the Production of Lead Plates or Electrodes for Secondary Batteries, and the Connections, Straps, or Lugs to the same. P. J. Davies, London. Eng. Pat. 21,031, December 24, 1890.

This patent is for mechanical means of producing such deeply-grooved plates as are used for Epstein electrodes. The grooves may be formed by casting in moulds, by pressure between dies, by rolling or ploughing out. The moulds or dies are formed of a number of steel laths fastened together, those which have to form the grooves in the electrodes being, of course, wider than the others. Rolls are made in a similar way by stringing together washers, those for forming the grooves being of larger diameter than the others. Very numerous drawings are given illustrating the details.—E. T.

Improvements in Galvanic Batteries for Producing Constant Currents. W. Wensky, Berlin, Germany. Eng. Pat. 49, January 1, 1891.

This cell is designed for the production of constant currents for a considerable length of time. A plate of copper placed horizontally is covered with copper subchloride. Above this is supported, between suitable osmose cloths, first a layer of powdered zinc and then a zinc plate. The electrolyte is a 40 per cent. solution of zinc chloride containing 1 per cent. of mercury perchloride. A number of such cells are made up into a single vertical block by the help of rubber rings. In the decomposition of the subchloride, copper is deposited on the copper plate, and zinc chloride formed.—E. T.

Improvements in Electric Cells or Batteries. H. T. Eagar, Canterbury, and R. P. Milburn, Newcastle-on-Tyne. Eng. Pat. 899, January 17, 1891.

An electrolyte suitable more especially to those cells which contain aluminium as one electrode (Eng. Pat. 6924 of 1890), is composed of sodium bichromate, 3 oz.; water, 120 oz.; sulphuric acid (commercial), 8 oz.; hydrochloric acid, 15 grains. The proportions may be varied, and a suitable quantity of ammonium bichromate used instead of the sodium salt.—E. T.

Improvements in Primary Batteries. S. W. Maquay, London. Eng. Pat. 1035, January 20, 1891.

This patent relates to the raising and lowering of battery elements by means of a chain and roller or sprocket wheels, and also to clamps for holding the zinc plates and allowing of their rapid replacement.—E. T.

Improvements in Galvanic Batteries. F. Poudroux, Paris, France. Eng. Pat. 3198, February 21, 1891.

In an outer jar is placed a cylinder of carbon, and within this a porous pot containing a zinc cylinder; inside this a second porous pot containing a carbon rod. The inner carbon is bathed in water, 20 parts; potassium nitrate, 2; manganese dioxide, 1; sodium bichromate, 3; sulphuric acid, 2 parts. The solution round the zinc consists of water, 20; sal-ammoniac, 3; potassium nitrate, 2 parts. Surrounding the outer carbon is a solution of sodium bichromate with one-tenth part by weight of sulphuric acid. It is claimed for this cell that it will last a very long time without attention, and that by the employment of a solution containing no acid, the zinc very seldom requires amalgamation.—E. T.

An Improved Galvanic Battery. W. H. Manns, London. From G. A. Smith, Halifax, Canada. Eng. Pat. 3417, February 25, 1891.

This invention consists in a battery composed of zinc and carbon elements so connected to a plate working vertically on guide bars, that by means of a lever placed on the outside of the enclosing case the plates can be raised out of or immersed in the electrolyte.—G. H. R.

Process for Clarifying and Bleaching Tanning Extracts or Tanning Liquors. A. Voesting, Düsseldorf, Germany. Eng. Pat. 4385, March 11, 1891.

See under VI., page 237.

A New or Improved Solution or Electrolytic Fluid for Galvanic Batteries. W. J. Engleline, Byfleet. Eng. Pat. 4781, March 17, 1891.

The invention consists of a solution for galvanic batteries composed of sulphuric acid, hydrochloric acid, bichromate of soda, and water.—G. H. R.

Improvements Relating to the Production of Porous Materials, and to the Manufacture of the same into Electrodes or Plates for Electric Batteries. H. H. Lake, London. From E. A. G. Street, and A. W. Desruelles, Paris, France. Eng. Pat. 1781, March 18, 1891.

This invention consists in making plates for batteries by mixing intimately one of the oxides of lead, or manganese, with "any suitable calcareous or porous material" which is not attacked by the electrolyte to be used. The mass is made into a paste with albumen and moulded into plates, which are then heated to coagulate the albumen.

—G. H. R.

Improvements in Apparatus for Preparing Bleaching Solution and Bleaching Powder by Electrolysis. E. E. Lever, Altrincham. Eng. Pat. 11,620, July 8, 1891.

An arrangement of tank and electrodes is described for effecting the decomposition of brine or sea-water. The tank may be made of cast iron preferably, with a porcelain porous partition between the two compartments. The chlorine is led into a chamber containing lime to form bleaching powder. The whole vessel may be warmed by steam.—E. T.

Improvements in or Connected with Accumulators or Secondary Batteries. H. Hauser, Madrid, Spain. Eng. Pat. 14,702, August 31, 1891.

According to this invention the plates are composed of a number of troughs arranged horizontally one over the other in a frame, and connected at their ends to its vertical sides, one of which is prolonged and forms the terminal. The troughs, which are made of an alloy of lead and antimony, are filled with the active material, which is preferably some oxide of lead.—G. H. R.

Obtaining a Fluid for Primary Batteries, and Utilising the Waste Products of such Batteries. H. H. Leigh, London. From J. B. Gardiner, Nyack, U.S.A. Eng. Pat. 16,487, September 29, 1891.

This patent is to reduce the cost of working by the employment of a cyclic method. A chromic acid cell is given as an example. Lead chromate is treated with sulphuric acid, giving chromic acid—*Part A*—and lead sulphate—*Part B*. The chromic acid is used in the battery, and when spent is treated with an alkaline carbonate, evaporated, and ignited; potassium chromate and zinc oxide are thus obtained. The latter is of immediate commercial value; the former is treated with *Part B* above—lead sulphate—with the production once more of lead chromate and potassium sulphate. The lead chromate may now go through the whole cycle again.

The method may be modified as follows: Chromate of lime and sulphuric acid give chromic acid and sulphate of lime. The spent chromic acid after use in the cell is treated with the sulphate of lime produced alone, or with carbonate of lime, dried, and ignited, with the production of chromate of lime once more and zinc oxide. The principle can be applied to a great number of salts.—E. T.

Improvements in Electric or Galvanic Batteries, and in Materials therefor. D. J. N. Lamb, Boston, U.S.A. Eng. Pat. 17,430, October 13, 1891.

The "active" material consists of a mixture of granules of potassium bichromate, copper sulphate, sal-ammoniac, manganese peroxide, lead shot, &c., some or all of which are rendered impervious to moisture by a coating of resinous or waxy material. A special form of cell is also described, in which this active material seems to surround zinc and carbon alike. The electrolyte may be water.—E. T.

Improvements in and Relating to Electric Batteries. B. Scheithauer, Halle-on-the-Saale, Germany. Eng. Pat. 17,994, October 20, 1891.

Oxygen is introduced into each cell of the battery in order that it may combine with the hydrogen formed at the negative plates, and so prevent polarisation.—E. T.

Improvements in Secondary Batteries. M. Waddell, J. B. Entz, and W. A. Phillips, Bridgeport, U.S.A. Eng. Pat. 18,431, October 27, 1891.

The positive electrode is made of copper wire surrounded with copper oxide, which is held on with a braiding of fine copper wire, the whole being covered with a braiding of cotton. Two such wires placed side by side are doubled on themselves and then turned backwards and forwards into a mat, one wire thick, with the four ends at the top. This mat is held in shape by stout insulated wires round the edges and along the faces. The negative electrode is a perforated sheet of iron doubled round the positive like the zinc of a Grove cell. The solution is sodium and potassium zincate. The binding wires mentioned above, which hold the mat in shape and also insulate the positive plate from the negative, are covered with a cotton braiding impregnated with whiting and silicate of soda. When immersed in the potassium solution the covering becomes very stiff and glassy. The iron negative electrode may be plated with nickel, tin, or any other suitable metal.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

The Solid Products which result from the Oxidation of Drying Oils. A. Lévache. Compt. Rend. 1891, 113, 136—139.

CLOEZ has shown that the products of the oxidation of drying oils consist of fatty acids together with a neutral insoluble body, to which Mulder has given the name of *Linorin*. When these oxidation products are treated with solvents, such as petroleum ether, ether, oil of turpentine, acetone, ethyl acetate, or carbon bisulphide, in the cold, the action is very slight, but on boiling the oxidised oil with a small quantity of the solvent, the solid product becomes more transparent, swells up, and gets broken up into fragments which form an elastic mass. If an excess of solvent be used it becomes coloured yellow, and when evaporated leaves a solid sticky residue, which softens at a very low temperature. The insoluble portion is a friable, elastic mass. Mineral essences do not dissolve any portion of the oxidised oil, but only break it up forming an opaque greyish mass of a cohesive nature.

The author points out the similarity between the physical properties of the oxidation product of drying oils and those of caoutchouc, and considers that the soluble portion of the former could be employed with advantage in an analogous manner to caoutchouc for manufacturing purposes.

—C. A. K.

On the Polymers of Ricinoleic Acid. Scheurer-Kestner. Comp. Rend. 1891, 113, 201—203.

THE author has already shown that Turkey-red oil, prepared by treating castor oil with monohydrated sulphuric acid, contains polymers of ricinoleic acid (see this Journal, 1891, 471).

Polymerisation may be effected also by heating with water alone. The acid product, obtained by heating with water at 150° C., has, when freed from glycerol, an oily consistency, and is heavier than ricinoleic acid; according to the molecular weight it is a mixture of ricinoleic and diricinoleic acids. With increase of temperature polymerisation is carried further, as far as tetra- and penta ricinoleic acids.

Diricinoleic acid and its congeners resist saponification by soda, decomposition not being effected below 100°. The molecular weights were determined with acids dried by calcium chloride, the solvent used for products up to diricinoleic acid being acetic acid, and for products above this benzene.—T. L. B.

Varnishes. Dr. Hugo Müller. Nature, 1892, 45, 241—245.

AFTER pointing out that mastic varnish is simply a surface-varnish, and should never be mixed with oil varnishes, he proceeds to speak of fat or oil varnishes, which are of greater importance than mastic varnish. They are compounds of the harder resins, such as amber and the different kinds of copals, with linseed oil, and diluted with oil of turpentine. They form in reality the vehicle or medium for modern oil-painting, and consequently furnish ultimately the matrix in which the particles of the colour are embedded and held together. Next to the stability of the colours, it is then the durability of this varnish medium, in combination with dry linseed oil, on which the permanency of the oil-painting mainly depends. On the assumption that the valuable qualities of the hard resins are maintained in the varnishes derived from them, it is understood that artists' varnishes are prepared only from the hardest and most tenacious kinds of resins. Unfortunately, these are the most unmanageable and the least soluble, and require the highest degree of heat to bring them into fusion for the purpose of effecting the combination with the linseed oil and oil of turpentine, in the process of making varnish. Even the most powerful solvents, such as acetone, ether, benzene, chloroform, aniline, and phenol, have only a limited solvent action upon amber or the harder semi-fossil kinds of copal; and their solution can only be effected after they have undergone a profound change by fusion or otherwise. In opposition to what is generally stated, neither amber nor the semi-fossil hard copals are fusible in the ordinary sense of the word; for they require to be kept at a high temperature, in suitable vessels, for a considerable time before they become gradually liquefied by the action of the heavy oily products of their own decomposition. Amber and copal, when thus once melted, are completely changed; they are now fusible at a low temperature; they have become readily soluble in ordinary solvents, and miscible with heated linseed oil; but at the same time the original hardness of the resin is greatly reduced, and the colour has become of a more or less dark tint.

It remains to be proved whether much is gained by using the very hardest resins, instead of softer and more tractable kinds which yield lighter-coloured varnishes; and this is a subject which, in Dr. Müller's opinion, deserves investigation. Varnish-making is still a secret trade, and the nature of varnishes, more than any other artists' materials, is involved in much obscurity. There are no chemical methods known for ascertaining the nature or proportion of the ingredients used in their preparation, and as time is the most important factor in proving the quality of varnishes, direct practical experimental tests may be misleading.

A new process for making varnish, said to be in use on the Continent, consists in heating the resins with the solvents in autoclaves under high pressure; and there are also processes recommended which seem especially adapted for those who wish to make their own varnishes on a small scale. These latter depend on the peculiar change which the hard copals undergo when exposed for some time, in a state of very fine powder, to the action of hot air, whereby the resin is rendered more soluble without becoming much discoloured. Professor Church (*Chemistry of Paints and Painting*) (this Journal, 1892, 185) describes such a process, in which the finely-powdered resin, after having been exposed for some time to the action of air at a temperature of 220° C., is first dissolved in chloroform, then mixed with oil of turpentine, and after the chloroform has been distilled off, the resulting solution is gradually incorporated with the

drying linseed oil. Although 220° C. is repeatedly mentioned as the temperature to which the powdered resins have to be exposed, Dr. Müller suggests that this must be a mistake. Neither amber nor the copals will endure this temperature for any time without melting and becoming of a dark brown colour, or otherwise decomposed.

On the other hand, Dr. Müller has found that the various kinds of copal, which, by exposure in a finely-powdered condition for some weeks to the action of hot air in a steam closet, have become readily soluble in chloroform or acetone, are nevertheless almost entirely precipitated again on adding oil of turpentine or benzene to such a solution, and no amount of digestion, either with or without linseed oil, will re-dissolve them. Amber thus treated behaves in a similar manner, but the amount rendered soluble in chloroform or acetone is much smaller. It would, then, appear that this matter requires some further elucidation before this new process can be made readily available.

There are no special tests for ascertaining the quality of a varnish. Spreading a thin layer on a sheet of glass, and then observing the character of the film produced on drying, seems all that can be done. It ought to become dry to the touch within eight or ten hours, and not become fissured even when exposed to sunshine during a year; nor should the surface become dull during the appearance of "bloom," caused by the minute exudation of solid fatty acids originating from the linseed oil employed in its preparation.

As the drying of the solution of resins in a volatile solvent depends solely on the volatilisation of the solvent, this process is accompanied by a shrinkage of the body of the varnish which sets up a tendency to breaking-up of the surface. Linseed oil, on the other hand, becomes dry or solid in consequence of combining with a large quantity of oxygen, and this is attended by an increase in bulk. It follows that as long as a sufficient proportion of oil is in combination with the resin the tendency to crack is compensated, but if the artist, from habit or other reasons, uses with his colours a medium deficient in oil, he encounters the risk of the body of his paintings becoming fissured in the course of time, and readily subject to the destructive action of the atmosphere.

There is still much to be learned with regard to the chemical processes involved in the so-called drying of linseed oil, and this subject deserves a thorough re-investigation in the light and with the means of modern chemical research. It is, for instance, a well-known fact that linseed oil under certain conditions becomes itself a most powerful oxidiser—so much so that canvas or paper soaked with it will become destroyed in the course of time; and it seems that this effect is especially marked when oil of turpentine has been used along with it. It is quite conceivable that this activity of linseed oil may be one of the agents at work in the deterioration of oil-paintings; but whatever dangers may arise from this, the use of linseed oil cannot be dispensed with. It is otherwise with oil of turpentine, for which a very much superior substitute might be found in the higher members of the benzene series, which could now be obtained at a sufficiently moderate cost if a demand for them should arise. These hydrocarbons, whilst indifferent to the action of atmospheric oxygen, possess greater solvent power than any other, and on this account they are also well adapted for the preparation of varnishes. But for this latter purpose a still more suitable vehicle will be found in the amylac acetate, which dissolves even the hardest copals almost entirely after having been previously finely powdered and kept for some time in a hot closet. In this way excellent varnishes may be produced.

On the Durability of Modern Pigments in Oil. A. P. Laurie. J. Soc. Arts, March 11, 1892, 383—387.

PROFESSOR CHURCH, in his recent book on the "Chemistry of Paints and Painting" (this Journal, 1892, 185), has drawn up a selected palette of 25 pigments suitable for oil-painting. He divides them into two groups.

Section I. contains:—

Flake white.	Vermilion.
Cadmium yellow.	Madder carmine.
Cobalt yellow.	Light red.
Yellow ochre.	

Viridian.	Raw umber.
French ultramarine.	Cappagh brown.
	Ivory black.

Section II. contains:—

Raw sienna.	Purple madder.
Naples yellow.	Madder brown.
Baryta yellow	

Green oxide of chromium.	Cobalt blue.
Terre verte.	Prussian blue (insol.).
Malachite.	Burnt sienna.
Emerald green.	Caledonian brown.

This selected palette is the outcome of many years of experimenting and of useful observation of the behaviour of pigments. It is also sufficiently complete to supply all that is needed in painting a picture. On the other hand, it cannot be regarded as final. Doubtless, as knowledge increases, certain pigments will be excluded from this list, and others introduced.

The pigments which require careful preparation and careful testing before being finally included, are cadmium yellow, cobalt yellow, vermilion, madder carmine, French ultramarine, Naples yellow, baryta yellow, purple madder, madder brown, malachite, emerald green, Prussian blue—all these pigments are artificial except malachite, which is of little importance; and much will depend on the method of preparation, careful washing, exclusion of dangerous impurities, and freedom from gross adulteration. The other pigments in the list are permanent, if genuine; and therefore all that is necessary is to look out for adulteration.

To take then the yellow pigments mentioned in the first column, and to begin with *Cadmium Yellow*, careful readers of Prof. Church's book will find that he refers to only one shade of this yellow as being perfectly safe, an orange-yellow shade. The pale cadmiums are notoriously fugitive, and contain free sulphur, while the deep orange cadmiums seem apt to change into the yellow varieties.

The endeavour has been made to obtain a cadmium of a pure light yellow, which shall contain no such objectionable constituent as free sulphur, and shall also be molecularly stable. Some lately prepared was subjected to a dull red heat before grinding. This ought to increase molecular stability, and would, of course, prove destructive to pale cadmium, made the usual way. The pigment is probably worthy of a trial as it ought to be stable.

Cobalt Yellow (Aurcoline).—This pigment (a nitrite of cobalt and potassium) is prepared from a recipe very similar to the one given by Prof. Church. After thorough washing and grinding in oil it appears unaffected by 12 months' exposure out of doors towards the south; so that as far as the tests go, confirmation is afforded of Prof. Church's good opinion of it.

Yellow Ochre.—Attention was directed to a most objectionable adulteration of yellow ochre with lead chrome yellow. Out of seven samples of "Oxford ochre" sent by wholesale dealers in pigments, two contained chrome yellow. One of the two consisted very largely of whitening, tinted with chrome and mixed with a small quantity of a pale ochre. The result was a sample which looked as bright as the best samples of genuine Oxford ochre. Prof. Church mentions adulteration with yellow lake—no such case has yet been met with.

Vermilion.—Many English samples were found to contain alkaline sulphide, and genuine Chinese vermilion was preferred. The following are the percentages of ash found in different samples of Chinese vermilion obtained direct from China:—

(1.)	(2.)	(3.)	(4.)	(5.)	(6.)
0.1	0.1	0.06	0.12	0.06	0.04

Some of the English vermilion can be very much improved by washing with weak acid, as the following analysis shows :—

	Per Cent.
Ash before washing.....	0.52
Ash after washing.....	0.14

All vermilion, including the best Chinese vermilion, blacken in sunlight, but are probably stable pigments when exposed to the diffused light of a room or gallery.

Madder Carmine.—The madder lakes experimented on were of the author's own making. They were prepared by dyeing well-washed alumina with artificial alizarin, and again thoroughly washing. A purple, a ruby, and a rose madder were prepared. After a year's exposure the purple had, possibly, lost a little, the ruby was unchanged, and the rose was very slightly faded, and had become purpler in tint. They were all, practically, unaltered, but with a slight advantage in favour of the ruby madder.

The only other pigment open to question in this palette is French ultramarine. No experiments on this pigment were made.

Naples Yellow.—No difficulty was found in preparing a real Naples yellow, that is a compound of oxide of lead and antimony of a fine colour, but it was not exposed for a sufficient time to test its durability.

Baryta Yellow, or Lemon Yellow.—Church points out that lemon yellow is often a strontium, not a barium chromate, and that the barium chromate is much the most permanent of the two. Author therefore only experimented on the barium chromate, preparing it himself. It seemed to lose slightly in brilliancy after 12 months' exposure. As lead chrome and Prussian blue are known to be mutually destructive, it was thought as well to test a mixture of barium chrome and Prussian blue. A bright green was produced, only slightly dulled by 12 months' exposure. Here and there the Prussian blue seemed to have faded, causing the yellow to show up through it a little more, but they did not seem to have any mutual injurious action.

Brown Madder of author's own making was not tested for a longer period than six months, for that period it was not affected.

The two next pigments of doubtful stability were malachite and *Emerald Green*. Malachite is little used, and was not experimented on. Elsewhere the property which emerald green possesses of slightly dissolving in the linseed oil, and slowly diffusing through it after it is dry, is described. It is, of course, fatal both to cadmium yellow and vermilion, turning them black. For this reason, it is better rejected, or, if used, only occasionally by itself, and far away from any cadmium yellow on the picture. Author advises the introduction of cobalt green into the palette. It is a durable and beautiful pigment.

Prussian Blue.—It is very difficult to buy Prussian blue that has been properly washed. It is apt to contain as much as 0.3 per cent. of free sulphuric acid, and often large quantities of potassium ferrocyanide. English makers are, in the author's experience, peculiarly careless; and he has found it best to buy Prussian blue in Germany. It is troublesome to make. The blue he has obtained from there never contains more than 0.01 per cent. of free acid, so that it is easily washed sufficiently. He had some of a perfectly washed blue exposed for 12 months. It was found to be faded somewhat, and had become greener in tint. It must be remembered, however, that, in the dark, Prussian blue recovers; so that it should be stable in an ordinary room. It may be mixed with cobalt yellow with impunity. All the other pigments in this palette are of undoubted stability, and are beyond question.

In the course of the notes, more than once the effect of light on these pigments has been referred to. The method of testing this was as follows :—An attic window looking nearly due south was selected, and outside it a wooden frame was hung, into which glass plates (half-plate size) could be slid. After preparing, washing, and drying a pigment, it was ground in pure cold-pressed, sun-refined

linseed oil, and rubbed out on two glass plates, getting the two patches of colour to look as nearly the same as possible. Both were put away to dry, and thereafter one plate was slipped into the frame and the other put away into a plate box. In this way the plate outside was exposed to all the weather and sun for 12 months, from September to September. The pigments tested were :—

TWELVE MONTHS.

Ruby madder.....	Unchanged.
Rose madder.....	More purple, very slightly faded.
Purple madder.....	Perhaps very slightly faded.
Cobalt yellow.....	Unchanged.
Lemon yellow (barium).....	A little duller.
Vermilion (Chinese).....	Black, or dirty brown.
Prussian blue.....	Faded, greener.

SIX MONTHS.

Brown madder.....	Unchanged.
-------------------	------------

These tests were of such exceptional severity, the exposure being outside, that probably none of these pigments should be removed from the selected palette, as they have practically (with the exception of vermilion) proved permanent. The reasons for not distrusting vermilion have been given elsewhere. As far then as the experiments have gone, the author would only exclude emerald green from this palette, provided the pigments mentioned are properly prepared, and with such restrictions, as the avoidance of impure vermilion and of pale cadmium yellow, as at present manufactured. Of the other pigments, the most affected by exposure (after vermilion) is Prussian blue. Of the other blues, of course cobalt blue is perfectly safe, but French ultramarine requires careful testing.

On the whole, this palette seems a very trustworthy one, and not at present open to much improvement. There are, however, various pigments excluded which are worthy of further trial, and may ultimately be re-introduced.

In all these experiments the pigments have been merely ground in pure oil. Different vehicles have a powerful influence on the durability of many pigments, and are worthy of special study.

The results may be briefly summed up as follows :—Linseed oil is permeable by moisture and gases, and consequently affords poor protection to pigments liable to be affected by moisture or certain gases.

The dissolving of resin in the oil, so as to make oil varnishes, such as copal-oil varnish and amber-oil varnish, has little or no effect in protecting the pigments, the moisture still penetrating.

Pure resin, when made into vehicles by solution in volatile liquids, and natural varnishes or balsams, such as Venice turpentine, *oleo de abezzo*, and others, do protect very effectively, excluding moisture and gases, and enhancing the durability of the pigment under adverse conditions.

(This probably accounts for the durability of most coloured lacquer work from Japan, when natural varnishes are used; and there is some historical evidence to show that balsam was largely used by both Flemish and Italian painters on vehicles.)

Certain pigments are soluble in linseed oil. For instance, verdigris is readily, emerald green slightly, soluble. Such pigments diffusing through the oil may be very destructive.

They are not soluble to the same extent, if at all, in resin. These results, the author hopes, may lead to the discovery of an improved medium, which will protect and isolate pigments ground in it, and so add to the durability of pictures.

In the discussion, Mr. F. Shields asked whether, in regard to the action of sulphuretted hydrogen in turning chrome yellow black, the lecturer had tried the effect of

strong electric light in reproducing the yellow colour, after it had been turned black. He imagined, as the arc light was extremely strong in active rays, that, after the exposure of a few hours to a strong arc light, one could definitely decide whether it were likely that the colour would be restored by sunlight. In the case of white, the electric light restored the colour sooner than the sunlight; at least such sunlight as they were able to get in the neighbourhood of London. His attention was first directed to this matter through some experiments tried by a friend in connexion with phosphorescence.

Mr. Laurie said the suggestion had not occurred to him, and it seemed a very good one.

Mr. Wollaston asked whether it would not be possible to produce a vermilion, by the aid of hydrogen sulphide under pressure, so as to avoid the alkaline sulphates.

Mr. Laurie said these Chinese vermilions were prepared by sublimating the sulphur and mercury together, and then one got the red sublimate on the top of the crucible; but he had not the faintest idea what would be produced by acting upon mercury and hydrogen sulphide under pressure.

PATENTS.

A Process for Printing on Celluloid, Ivory, Horn, and like Substances. A. A. C. de Coëtlogon, Paris, France. Eng. Pat. 5586, March 31, 1891.

A FINE close grain is produced on the surface of the material, either by hand or by mechanical means, such as the sand blast. The surface is then washed with water or alcohol, and covered with a varnish consisting of two parts of fatty varnish, one part of white copal varnish, and one part of rectified essence of turpentine or lavender, " &c." The varnish is rubbed off and thus made to penetrate into the graining while it is removed from the surface. An impalpable powder of equal parts of sulphate of magnesia and sulphate of baryta, with or without colouring matters, is now applied and allowed to remain on the surface for some hours, after which the surface is thoroughly wiped and subjected to any known satining process. Printing upon such a surface is as easily and effectively accomplished as upon paper.—A. G. B.

Improvements in Size. J. Shepherd, London. From A. Krizek and R. Esché, Geneva, Switzerland. Eng. Pat. 12,331, July 21, 1891.

4·375 kilos. of "amidin" are moistened with a portion of 93·875 kilos. of water; there is then added 0·100 kilo. of "acid of salicylicum," to which 1·375 kilos. of "sodium hydricum (hydrate of soda)" have been added, in small quantities; the remainder of the water is then stirred in little by little. An addition of 0·150 kilo. of "chrysoidin" and 0·125 kilo. of ether ("spiritus atheras") completes the manufacture. All the ingredients are used cold.

It is claimed that the new size produces the same effect as two to four coats of animal size.—A. G. B.

Improvements in the Manufacture of a Hard Insulating Material. R. Pape, Berlin, Germany. Eng. Pat. 20,407, November 24, 1891.

See under XI., page 249.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

The Weighting of Skins. W. Eitner. Der Gerber. 14, 27.

SKINS which have been weighted with sugar and dried in air easily mould and ferment; this is prevented by heating the skins to 50°—60° for 6—10 hours, the glucose changing to the less hygroscopic anhydride. The presence of sugar may be quantitatively ascertained by treating 1 gm. of the finely-divided leather with 10 cc. of water for five minutes; the solution is then shaken with freshly ignited magnesia until the liquid becomes pale, the filtrate is then treated with 2—3 drops of a 15—20 per cent. alcoholic solution of α -naphthol and twice its volume of concentrated sulphuric acid. When sugar is present a deep blue-violet colouration is produced, and on addition of water a blue precipitate is thrown down (Molisch's reaction). Epsom salts, barium chloride, and a mixture of Epsom salts and glucose are also employed as weighting materials. Skins yielding more than 3 per cent. of ash ought to be regarded as weighted.

—J. C. C.

PATENTS.

Improvements in and Relating to the Waterproofing of Leather. O. Brunner, Manchester. Eng. Pat. 3910, March 4, 1891.

THE waterproofing solution consists of 1 oz. of finely-divided Castile soap with 4 oz. of turpentine oil. Five ounces of such solution are said to be sufficient for the soles of two pairs of boots; it is spread over the surface of the soles with a brush, in successive coats. A fixing mixture of 2½ oz. of concentrated silicate of soda to 3 oz. of linseed oil is then applied, 5½ oz. of the mixture being required for the two pairs of soles. Each coat is allowed to dry before another is applied and the leather is finally exposed in a warm place for three or four days. A further fixing may be applied by immersing the soles in a solution of 1 oz. of bicarbonate of soda in 4 oz. of water for a quarter of an hour; but this is not necessary. The mixtures must be shaken immediately before use.—A. G. B.

Process for Clarifying and Bleaching Tannin Extracts or Tanning Liquors. A. Foesling, Düsseldorf, Germany. Eng. Pat. 4385, March 11, 1891.

XV.—MANURES, Etc.

The Sources of the Nitrogen of our Leguminous Crops. Sir J. B. Lawes and J. H. Gilbert. Jour. Royal Agric. Soc. 1891 [3], 2, 657—702.

THE scientific interest and the practical value of leguminous crops depend largely on the amount of nitrogen they contain, on the sources of this nitrogen, and especially on the great differences in these respects between them and the other agricultural crops. Thus, the grain crops, the root crops, and potatoes, all of which yield a comparatively small amount of nitrogen over a given area, and contain a com-

paratively low percentage of nitrogen in their dry substance, and which yield comparatively large amounts of non-nitrogenous products—carbohydrates—are especially benefited by the application of nitrogenous manures, although the increased produce is characteristically non-nitrogenous. Leguminous crops, on the other hand, which are characterised by their higher percentage of nitrogen, and which accumulate more nitrogen over a given area of land than any other crops, are comparatively little benefited by direct nitrogenous manuring.

Boussingault's experiments and those made at Rothamsted in 1858–59, in which the action of electricity and of microbes was excluded, showed conclusively that neither non-leguminous nor leguminous plants can fix free nitrogen under these conditions. And the evidence now at command still justifies the conclusion that, except in the case of the *Leguminosae*, free nitrogen is not available for agricultural plants. With regard to the *Leguminosae*, the authors have long admitted that the whole of their nitrogen could not be accounted for in a satisfactory manner. The results of Hellriegel and Wilfarth, showing that certain leguminous plants may acquire nitrogen brought into combination under the influence of lower organisms, were obviously of great importance, and led the authors to make experiments on similar lines. The first set of experiments (in 1888) included peas, yellow lupins, and blue lupins, which were grown:—No. 1 in washed sand with mineral manure, Nos. 2 and 3 in the same sand with minerals, but infected with soil organisms, No. 4 in soil. The peas, which grew well, gave very definite results, showing an increase of growth and considerably increased nitrogen fixation, under the influence of soil-extract seeding. The second series of experiments included peas, beans, vetches and lupins (as annuals), white clover, red clover, sainfoin and lucerne (as plants of longer life). The white clover experiment is still going on. A white sand was used which, after being well washed, was sufficiently sterilised by heating for some days in a water-oven. The results are very definite and striking and abundantly illustrate the fact that under the influence of suitable microbe-seeding there is nodule-formation on the roots, and coincidentally, increased growth, and gain of nitrogen. Where no soil-extract was given no nodules were found on the roots and the growth was very slight and contained only about as much nitrogen as was contained in the seeds sown. Noble's recent experiments indicate that there are several kinds of nodule organisms, and that those organisms are most beneficial to a given plant which have been obtained from the nodules of a similar plant. The observation made by Hellriegel, and at Rothamsted, that the extracts of all soils are not equal as regards nodule production, and the fact that the nodules on the roots of different plants differ widely from each other in form and in their distribution, seem to lend support to this view. Besides the strictly quantitative experiments above described, another set of experiments was made in which the same four annuals, and the same four plants of longer life, were grown in sand to which soil-extract was given and in soil, in pits so constructed that the plants could be taken up and their roots examined at three (or four) different periods of growth. It was found that when grown in sand infected with soil-organisms, the infection was more local and limited than was the case in soil; in sand the nodules were fewer, but of great size; in soil, smaller but more numerous. The analyses made with the nodules from the roots of annuals indicate that at the ripening period the nodules had lost both in dry matter and in nitrogen; in the case of plants of longer life, some of the nodules appeared to have become exhausted, whilst others, doubtless new and active, were richer in nitrogen.

The results of both sets of experiments make it probable that free nitrogen is fixed in the course of the development of the organisms within the nodules, and that the resulting nitrogenous compounds are absorbed and utilised by the host.

With regard to the practical aspects of the subject, Schultz of Lupitz has for years devoted a considerable area of poor sandy land to the growth of leguminous crops by means of kainite and phosphatic manures; and he found the land very much enriched for subsequent corn and other crops. The system is extending in Germany and is being

studied in Hungary. In this country Mr. Mason of Eynsham Hall, Oxfordshire, who commenced, in 1889, experiments with various *Leguminosae* in small plots, and afterwards in specially-built tanks, has now devoted about 200 acres to the practical application of facts recently brought to light regarding nitrogen fixation, his idea being to grow nitrogen-accumulating crops for home consumption and afterwards nitrogen-consuming crops for sale.

It is clearly established that there is a great gain of nitrogen under some conditions, and that the infection of the soil and of the plant is essential to success. It may also be concluded that the soil may be duly infected for one or more descriptions of plants but not for others. Land which is, so to speak, quite exhausted so far as the growth of one leguminous crop is concerned, may still grow very luxuriant crops of another description of the same family, but of very different habits of growth, and especially of different character and range of roots. This, though more or less due to other causes also, is nevertheless in some cases doubtless dependent on the existence, the distribution and the condition of the appropriate microbes. In any system involving a more extended growth of leguminous crops it will be necessary to have a considerable variation in the description of plant grown. It will generally be necessary to give liberal applications of potash and phosphate manures and to chalk or lime the land for the leguminous crop. Then the question would arise, how long the leguminous crop should occupy the land, to what extent it should be consumed on the land, or the manure from its consumption be returned; or under what conditions the whole or part should be ploughed in? Lastly, such a system would probably benefit light and poor soils more than the heavier or richer soils.—N. H. J. M.

Behaviour of Tricalcium Phosphate towards Carbonic Acid and Ferric Hydroxide. G. v. Georgievics.
Monatsh. 1891, 12, 566–581.

The author describes a large number of quantitative experiments on the action of carbonic anhydride, alone and in the presence of ferric hydroxide, on tricalcium phosphate. It was found that tricalcium phosphate, suspended in water, is decomposed by carbonic acid in accordance with the equation—

in most of the experiments this decomposition was far from being complete.

When carbonic anhydride is passed into water containing tricalcium phosphate and ferric hydroxide in suspension the calcium salt is decomposed, and the phosphoric acid combines with the iron; under certain conditions the whole of the phosphoric acid is thus withdrawn from the calcium salt.

These results have an important bearing on the question of the use of phosphatic manures, as they show that in the presence of a sufficient quantity of ferric hydroxide and carbonic anhydride, the whole of the phosphoric acid in the calcium phosphate applied to the soil may finally become converted into phosphate of iron. Alumina, which doubtless acts in the same way as ferric hydroxide, plays nevertheless a less important part in decomposing the calcium phosphate, because, being the most powerful silicate base, it is formed by the weathering of rocks in comparatively much smaller quantities.

These experiments also afford an explanation of the fact that lysimeter- and drainage-water invariably contain only traces of phosphoric acid. In what way the phosphoric acid combined with the iron or aluminium in the soil can again be brought into solution is, as yet, unknown, although the fact observed by Tuxen, namely, that the combined phosphoric acid is more readily soluble in water containing sodium salts than in pure water, points to a solution of the question.—F. S. K.

Manufacture of Superphosphate from Ferruginous Phosphates. Schucht. Zeits. f. angew. Chem. 1891, 667—671.

SEPARATING the phosphoric acid and preparing from it alkaline salts, also treatment with acid alkaline sulphates have been suggested as means of converting ferruginous natural phosphates into superphosphates. The author draws attention to the properties and behaviour of the substances which render these particular phosphates unsuitable for the preparation of superphosphates in the ordinary manner. He maintains that they can all be decomposed by sulphuric acid with more or less facility, according to the character of the phosphate and the strength of the acid, the iron passing into solution partly as acid phosphate and partly as sulphate, inasmuch as much as 2 per cent. of the latter can remain in solution with the acid calcium phosphate; but then the iron sulphate, as far as the excess of acid permits, by reacting with this calcium salt gives rise to calcium sulphate, which in its turn draws water from the phosphoric acid holding the iron phosphate in solution, and consequently the latter is rendered insoluble. A similar effect is produced when the natural phosphate is imperfectly decomposed, as the undecomposed calcium salts attack the phosphoric acid required by the iron to hold it in solution, and so "revert" it. The author is, therefore, of opinion that if sufficient sulphuric acid is used to ensure the complete decomposition of the phosphate, and that sufficient excess of phosphoric acid to keep the iron in solution is maintained, there need then be no fear of reversion. Alumina is not regarded as exerting any direct influence on the reversion, and ferrous salts are stated not to act on acid calcium phosphate, so that when a solution of the latter salt is mixed with a ferrous salt no precipitation takes place until oxidation from contact with the air or otherwise has ensued. In order to make use of this reaction for preventing reversion the author suggests the following method for the preparation of superphosphates from ferruginous natural phosphates. Decompose portions of the phosphate in the presence of ammonium sulphate with the total quantity of sulphuric acid, then reduce with sulphurous acid, and as this produces a large quantity of sulphuric acid, mix the remainder of the phosphate with the reduced mass. Experimentally a phosphate containing per cent., P_2O_5 , 30.7; CaO , 39.2; Fe_2O_3 , 4.2; Al_2O_3 , 1.9; MgO , 0.6; CO_2 , 5.0; Fe , 1.1; and SiO_2 , 1.8, was employed, and 750 grms. finely pulverised was warmed with 880 grms. of sulphuric acid $60^\circ B.$, until decomposition was complete, then 100 grms. of powdered ammonium sulphate were put in, and 220 grms. of water saturated in the cold with sulphurous acid, added, = about 10 litres of this gas, really an excessive amount of it. The mass, a thin magma, was reduced by heating in flat closed iron vessels fitted with a safety-valve. Subsequently the excess of sulphurous acid was got rid of and the remaining 250 grms. of phosphate mixed in. After two weeks the superphosphate contained 14.2 per cent. of phosphoric acid with 13.8 per cent. soluble in water; after four and six weeks the total phosphoric acid was 14.3, the soluble 13.8 per cent. It is advantageous to use the more readily decomposable phosphates for the subsequent decomposition. The author gives figures for the manufacture on a large scale and for the production of the sulphuric acid required; also suggestions for the storage and economy of the sulphurous acid. The author does not consider that this ferrous superphosphate will oxidise readily, firstly, because it is dry, and secondly, because the ferrous particles would be protected by the gypsum; the admixture of bone-meal would still further lessen chances of oxidation. As regards its behaviour towards plants the author considers that in the quantities sufficient to supply the phosphoric acid to a crop, there would not be enough ferrous iron present to exert an injurious action.

The Baltimore Meeting of the American Institute of Mining Engineers. Eng. and Mining J. 1892, 228.

THE PHOSPHATE DEPOSITS OF FLORIDA:
G. H. ELDRIDGE.

After a topographical and geological description of Florida in which he said that the formation was of the Tertiary age, divided into Eocene, Miocene, Pleiocene, Post Pleiocene, and Recent, Mr. Eldridge said that the principal portion, as far as the phosphate deposits were concerned, was Eocene, the age of the friable white limestone underlying the surface being determined, without question, by its fossils. A portion of the Median portion had been metamorphosed principally by alteration into phosphate of lime. The Miocene limestones were confined to a small territory in the vicinity of Tampa Bay and the upper western portion of the State. These limestones were always bedded, whereas the Eocene was never bedded. But the Miocene limestone itself had suffered alteration to phosphate of lime, differing but little from that of the Eocene. The Pleiocene covers a large section of the State, the constituents being clay, marls, and limestones.

Phosphate deposits in the Recent are in the course of a number of rivers, where it occurs as pebble phosphate. The Lafayette occurring at the northern border of the State was a formation very interesting, since it was the southern continuation of the red clays and marls which extend from the Potomac.

There are four classes of phosphates, he said—the hard rock, the soft rock, the land pebble and the river pebble. The gradations from the laminated variety strengthen the theory of deposition, especially as specimens of rock entirely similar in appearance were found at the Mammoth Spring in the Yellowstone, where they were deposited by the geyser mineral waters. The origin of the phosphates is in doubt, but phosphate of lime is found in many sea plants and animals. To account for these deposits through deposition and substitution there are four requirements—phosphate of lime, carbonate of lime, water, and a reagent to dissolve those minerals. Evidence goes to show that the surface waters in Florida carry to-day large quantities of carbonate of lime, carbonic acid, the real solvent, and humic acid, derived from the soils. These waters may have passed through fissures, and the phosphate of lime deposited as the carbonic acid was neutralised by the limestone. The age, however, was the Eocene. The boulders were formed by cavities in the limestone, being filled with phosphate of lime and the exterior casing being washed away.

XVII.—BREWING, WINES, SPIRITS, Etc.

The "Ginger-Beer Plant" and the Organisms Composing it: A Contribution to the Study of Fermentation—Yeasts and Bacteria. F. Marshall Ward. Proc. Roy. Soc. 1892, 50, 261—265.

THIS organism occurs in semi-transparent yellowish aggregations or as a deposit at the bottom of the fermentations. It consists essentially of a symbiotic association of a yeast and bacterium and as met with naturally is invariably associated with other yeasts, bacteria, and moulds.

The two essential organisms are both new species.

The yeast (*Saccharomyces pyriformis*) is an anaërobic bottom yeast forming spores and developing large quantities of carbon dioxide, but very little alcohol; it has also an aerobian form of pyriform cells, whence the proposed name. It inverts cane-sugar and ferments the products, but does not ferment milk-sugar. At suitable temperatures it forms spores in 24—48 hours.

The bacterium (*Bacterium vermiforme*) occurs in the fermentation as rodlets or filaments, curved or straight, and encased in a thick firm gelatinous sheath, and is markedly anaërobic, the best results being obtained by cultivating in carbon dioxide under pressure. The filaments or rods

eventually break up into cocci, which escape from the sheath, become free, and divide rapidly like ordinary bacteria.

The "ginger-beer plant" has been synthesised by mixing pure cultivations of the yeast and bacterium; the association of these two acts much more vigorously than each one separately.

Of the other organisms found in the fermenting liquid, two (*Mycoderma cerevisia* and *Bacterium aceti*) were always present, and the following very frequently: a pink yeast, a small acrobian top yeast, *Saccharomyces cerevisia*, three or four rare yeasts; *Oidium lactis*, *Penicillium glaucum*, *Dematium pullulans*, other torulae and bacteria.

A full account of this research will shortly be laid before the Royal Society. — A. L. S.

On the Presence of an Aldehyde containing Four Atoms of Carbon in "Eau-de-Vie de Piquette." J. A. Müller. Bull. Soc. Chim. 1891, 6, 796—800.

Is an "eau-de-vie de piquette," distilled from an inferior wine obtained by washing pressed grapes with water, the author has detected a substance resembling in odour α -croton-aldehyde. The piquette in question had been accidentally rather excessively exposed to air and possessed a very disagreeable flavour, whilst the spirit itself was undrinkable. The aldehyde supposed to be present was converted into the corresponding acid by digesting the spirit on the water-bath with moist silver oxide. The liquid after concentration yielded on treatment with strong alcohol, a caseous white precipitate, possessing the formula $C_{11}H_{19}O_5Ag$. The acid itself formed a syrupy, strongly acid liquid, consisting, so far as could be determined from the small amount of material at the author's disposal, of γ -hydroxybutyric acid, $CH_3OH \cdot CH_2 \cdot CH_2 \cdot COOH$. All attempts to prepare the silver salt of this acid from α -croton-aldehyde by treatment with silver oxide failed, either silver crotonate or some compound containing a smaller percentage of carbon being obtained. Theoretically, by the simultaneous oxidation and hydration of α -croton-aldehyde, only α - or β -hydroxybutyric acid, or a mixture of the two, is obtainable. On the other hand, iso-croton-aldehyde, if it exist, might yield γ - or β -hydroxybutyric acid. — H. T. P.

The Manufacture and Properties of Fig Wine. A. H. Vogel. Zeits. f. angew. Chem. 1891, 641—643.

In a recent communication (this Journal, 1891, 718) Charles describes a method for the detection of fig-wine in admixture with grape-wine, based on the fact that the former contains mannitol. In recent years, figs have been largely employed in Portugal for the manufacture, not so much of wine as of a species of brandy, and this fact has induced the author to repeat Charles' experiments in order to test their correctness. Fig-wine was prepared from ripe second-year fruit, according to the process indicated by Charles. The wine obtained possessed a most agreeable, refreshing, acid flavour, and differed in no way from the local red grape-wine, except that its colour was less intense. The disagreeable smell peculiar to fresh figs had entirely disappeared. The wine (rather more than one month old) gave the following results on analysis:—

Specific gravity	1.023	
Alcohol	1.05	per cent. by weight.
Acid	0.52	" (as H_2SO_4)

The brandy distilled from the wine possessed a most agreeable flavour and smell. The author was unable to confirm Charles' statement that the syrup obtained by evaporation of the wine solidifies to a crystalline mass on standing in a cool place for some time. No crystallisation whatever was observed, and it was only after extraction of the syrup with alcohol, decolourisation with chateaul, and evaporation of the alcoholic solution, that a quantity of crystals were obtained. The crystals were by no means pure, but were contaminated with a brown syrup which

rendered their quantitative estimation impossible. Some of the wine which had been kept for three weeks longer in corked bottles had the following composition:—

Specific gravity	1.020	
Alcohol	4.20	per cent. by weight.
Acid	0.50	" (as H_2SO_4)
Ash	0.59	"
Extract	6.92	"
Phosphoric acid (contained in the ash)	0.05	"

The ash contained much CO_2 . On testing for mannitol practically the same result was obtained as before. Another portion of wine which had been exposed to the air from the beginning became covered with a white film and deposited a voluminous light precipitate, whilst at the edges of the vessel numerous worms, 4—8 mm. in length and strongly resembling "cheese-mites," were observed. At the same time a strong cheesy odour was developed, resulting, no doubt, from the decomposition of the mannitol.

In view of these results, the author is of opinion that the mannitol test for the identification of fig-wine is unsatisfactory. On the other hand, the determination of extract might be of value, for only a sweet grape-wine (of equal specific gravity) could contain so high an extract. The ash of fig-wine also considerably exceeds that of any grape-wine. — H. T. P.

New Experiments on the Effect which a Treatment with Tartaric Acid has on Brewery Yeast. E. C. Hansen. Zeits. f. d. ges. Brauwesen, 1892, 2—6.

In a previous communication (Carlsberg Mitteilungen, 3, Heft. 1), the author has described experiments made to test Pasteur's method for purifying brewery yeast by growing it in a solution of cane-sugar slightly acidified with tartaric acid. Duclaux, Velten, and others have of late drawn attention to this method and assert that it is as efficacious as that of Hansen (cultivation from a single cell).

In the communication above referred to the author described experiments with a view to testing the value of this method, and found that not only was it quite useless, but even harmful, as it led to a considerable increase in the proportion of wild yeasts.

Velten has criticised these experiments, objecting that the mixture of yeasts used by Hansen contained considerably larger amounts of wild yeasts than would be present in a brewery product, and that the temperature at which the cultivations were made (25° C.) was too high.

In order to leave no shadow of doubt on these points, the author has made further experiments.

A yeast was obtained from a beer which had been brewed with pure yeast, the beer being perfectly satisfactory in every way. The yeast on being grown on gypsum blocks at 25° C. produced few, if any, spores during six or seven days, thus showing that either very few or no wild yeasts were present.

Two series of cultivations of the yeast in the slightly acidified cane-sugar solution were made; one at the ordinary room temperature (about 17° C.) and the other at 5° C.

In the experiments carried on at the room temperature the yeast was so altered not only after 4 or 5 cultivations but even after 3 cultivations, and that after a final cultivation in wort a yeast was obtained which on a gypsum block at 25° C. showed a plentiful spore formation after 3—4 days, thus proving that a considerable quantity of wild yeasts were present. From a microscopic examination these yeasts appeared to be chiefly *Pastorinus* and *Ellipsoides*. After only two cultivations in the acidified sugar solution and a final cultivation in wort the pure yeasts still remained in excess.

The second series of experiments at 5° C. gave similar results, except that, of course, owing to the low temperature, the time required for the successive cultivations was longer.

These experiments leave no doubt as to the accuracy of the statement previously made, that this method of purifying

yeast is not only useless but absolutely noxious; in fact there is no antiseptic known which when added to fermenting liquids will kill all the wild yeasts and leave only those suitable for the manufacture of beer; yet there is no doubt that if yeasts contaminated with bacteria be cultivated in a slightly acidified solution of cane-sugar, most of the bacteria will die and only yeasts remain.

These experiments, besides accomplishing their primary object, have given us a method for easily analysing brewery yeasts. If successive cultivations of the yeast be made in acidified cane-sugar solutions, as employed in these experiments, any wild yeasts present will, in the final cultivation, bear a much greater proportion to the brewery yeasts than in the original, and will be easily detected under the microscope.—A. L. S.

On the Influence of Oxygen and Concentration on Fermentation. A. J. Brown. Proc. Chem. Soc. 1892, 107, 33.

THE author describes experiments on the reproductive power of yeast, from which it appears that all fermentable nutritive solutions encourage the increase in number of yeast cells to some fixed point beyond which they will not reproduce themselves; and he shows that if a greater number of cells be introduced into a fermentable liquid than the liquid could originally develop, no increase in number of cells takes place. As under conditions like these fermentation still proceeds vigorously, a number of disturbing factors which complicate the results obtained under ordinary conditions may be eliminated by using non-multiplying yeast cells.

A series of experiments are described in which fermentations were conducted in presence of large amounts of oxygen, whilst at the same time duplicate experiments were made in which oxygen was excluded: the same number of non-multiplying yeast cells being used in both cases, and all the other conditions, such as temperature and agitation, &c., being kept constant. Under these circumstances it was found that both equal numbers of yeast cells and equal weights in presence of oxygen exercised more fermentative power than when unexposed to its influence. The author is unable to reconcile these results with M. Pasteur's theory of fermentation.

Experiments carried out with a fixed number of non-increasing yeast cells also showed that the amount of sugar fermented in a given time by them did not depend on the concentration of the solution, but that within the limits of 20 and 5 per cent. solutions of dextrose, approximately the same weight of sugar was fermented. When the strength of a solution reaches 30 per cent. of dextrose fermentation proceeds much more slowly.

PATENTS.

An Improved Method of Increasing the Formation of Cells during the Process of Fermentation. G. F. Redfern. London. From J. Hradil, Alt-Döbern, Germany. Eng. Pat. 3207, February 21, 1891.

THE above object is said to be attained by the addition of "vegetable mucilage" to fermenting liquids, the incomplete fermentation of which is ascribed to a deficiency of "mucilage." The mucilage in question is prepared by boiling certain parts of plants, such as quince and flax seeds, *plantago psyllium*, *fagaceæ*, unicellular *algæ*, and other plants, the tubers of orchids, the roots of althea, &c., with water for a long time. The extract thus obtained is strained and concentrated, or reduced to complete dryness by evaporation. Vegetable mucilage when dry forms a horny mass, which swells up in water to a transparent, non-adhesive jelly, but does not dissolve. This jelly may be added either to the liquid to be fermented or to the fermenting agent itself, some indifferent substance likewise being added, if necessary, to effect the more complete subdivision of the jelly. The amount of mucilage to be employed varies greatly according to circumstances. In the case of a potato mash 25–30 grms. may be used per 1,000 litres of wort.—H. T. P.

The Manufacture of Charcoal from Sawdust, Wood Shavings, and the like, and the Treatment of Wine, Alcohol, Brandy, Cider, Beer, and other Matters therewith. F. L. Calmant, Paris, France. Eng. Pat. 3978, March 5, 1891.

THE charcoal is made by carbonising sawdust or compressed shavings in crucibles. When completely carbonised the charcoal is quickly crushed and sieved and preserved in an air-tight vessel. The temperature of carbonisation varies from 600–1,000 C. according to the use for which the charcoal is intended. Different kinds of wood are to be carbonised separately as they are suitable for different purposes.—A. L. S.

Improvements in Apparatus for Distilling and Rectifying. S. Pitt, Sutton. From "A. Savalle, Sons, and Co.," Paris, France. Eng. Pat. 21,708, December 11, 1891.

THE apparatus consists of a horizontal cylinder, divided into communicating compartments by discs; a shaft passes through the cylinder to which is attached in each compartment a disc with a paddle and scraper.

The liquid to be rectified is introduced at one end and steam at the other, and the rectified vapours and the waste escape at other openings.—A. L. S.

Improved Means and Apparatus for Rousing, Aërating, and Attenuating Brewers' Wort during the Process of Fermentation. C. F. Jolliffe, St. Helens. Eng. Pat. 22,124, December 17, 1891.

At intervals the wort is pumped from the bottom of the fermenting vessels into trays with perforated bottoms placed over the fermenting vessels; by this means the wort is well roused.—A. L. S.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A.)—CHEMISTRY OF FOODS.

Improvements in the Manufacture of Artificial Seltzer Water; Arrangement of the Syphon. M. de Pietra Santa. Compt. Rend. 1891, 113, 253.

THE Paris works employ the waters of the Dhuïs and of the Vannes, which are first subjected to repeated filtrations. The water is aerated by liquid carbonic acid by decreasing the pressure on the liquefied gas contained in cylinders from 12 or 14 to 8 or 9 atmospheres. The head of the syphon is composed of an alloy of pure tin, the use of lead being strictly prohibited. The central tube of the syphon is made of glass, and is held by means of copper in a cylindrical piston made of ebonite. The inside of the head of the syphon, as well as the supply pipe, are coated with a glaze of fine porcelain, so that the water has no contact with metal in any part of the syphon bottle.—C. A. K.

PATENTS.

Improvements in and relating to Sterilising Apparatus. E. Cohn, Berlin, Germany. Eng. Pat. 20,348, December 13, 1890. (Reprint.)

THE patent refers to various forms of apparatus for automatically closing bottles of which the contents have been sterilised. In its simplest form the device consists of a vertical bar passing through and connected with the lid of the sterilising box, and having at its lower end a V-shaped trough-piece by which the closing-pieces of the bottles can

be actuated. By regulating the position of the vertical bar relative to the lid, the closing of the bottles can be effected earlier or later than that of the sterilising vessel. A more complex form consists of a sterilising chamber containing a wagon running on rails within it, and provided with spaces for as many bottles as may be necessary. The closing-pieces of the bottles are actuated by closing-bars, motion to which is communicated by a vertical rack turned by toothed segments working on a shaft running from end to end of the apparatus, the outer end of which passes through the door of the sterilising chamber, and is there connected with a lever, by means of which both it and the bolts closing the door of the chamber are controlled. The position of this lever relative to the spindle and the locking-bars of the door can be regulated so as to vary the relation of the time of opening the door to that of closing the vessels. In another arrangement which is figured and described, the closing of the bottles is effected by drawing the wagon containing them along the rails on which it runs by means of a horizontal spindle working in a nut, so that rollers carried on the closing-bars pass under cams depending from the roof of the sterilising chamber, whereby the closing-bars are forced down, and the closing-pieces thus given the requisite vertical motion. In this form of apparatus an automatic safety-valve, which by opening permits of the final rush of steam being greater than it otherwise would be, is provided. The invention described in Gronwald and Oehlman's patent No. 206 of 1890 is expressly disclaimed.—B. B.

Improvements in Making an Extract of Coffee, and a Confection of the same, and in Preserving Liquid Coffee Extracts. E. Sonstadt, Cheshunt. Eng. Pat. 21,019, December 24, 1890.

CERTAIN improvements are described relating to an apparatus and method for the manufacture of coffee extract previously patented by the inventor (Eng. Pat. 3172 of 1889; this Journal, 1890, 539). The improvements are as follows:—

1. The exclusion of air from the digester and evaporator by means of a current of carbonic acid gas or nitrogen, the former being preferable.
2. The use of butter, &c. as an "aroma-absorbing agent," and the subsequent employment of the product thus obtained in the manufacture of a coffee-confection by admixture with sugar and concentrated coffee extract.
3. The substitution of asbestos, glass-wool, &c. for animal or vegetable wool as an aroma absorbent.
4. The use of a long, shallow digester (admitting of a more rapid and complete extraction of the coffee) in conjunction with a comparatively small boiler, from which the extract is drawn off from time to time (preferably).
5. The preservation of liquid coffee extract by sterilisation at 100° C.

Full details of the method of producing liquid and solid coffee extracts and confection, as well as drawings of the necessary apparatus, are given.—H. T. P.

Improvements in Making an Extract of Tea, and a Confection of the same, and in Preserving Liquid Tea Extract. E. Sonstadt, Cheshunt. Eng. Pat. 21,106, December 27, 1890.

THIS invention is an addition to a previous patent (Eng. Pat. 20,182 of 1889; this Journal, 1891, 65–66). The modified process and apparatus here detailed are precisely the same as those given for the preparation of coffee extract (Eng. Pat. 21,019 of 1890; see preceding abstract).

—H. T. P.

Improvements in the Preparation of Peptone Extracts, and in the Application of the same to various Useful Purposes. M. P. Hatschek, London, G. A. Clowes, Needham, and L. Briant, London. Eng. Pat. 2207, February 6, 1891.

THIS invention forms an extension of two preceding patents (Eng. Pat. 3363 and 18,399 of 1888; this Journal, 1888, 859 and 1890, 84). The method, formerly described, of preparing malto-peptone extract, although preferably em-

ployed, may be varied, more or less water, or simply hot or cold water alone being used, with or without the addition of antiseptics, for extracting the malt-culms.

"Malto-peptone extract is used for the following purposes:—1. As a yeast food and stimulant. 2. As an addition to bakers' ferment and sponges, and for producing buns, rolls, &c. 3. As a direct addition to bread, cakes, biscuits, chocolate, &c., and other liquid and solid foods in order to raise their nutritive values." "The extract may also advantageously be used, either alone or mixed with oil, glycerin, &c. as a substitute for yolks of eggs in tanning and dressing leather. Further, it may be employed as a nutrient in pharmaceutical preparations, either alone or in admixture with malt extract, cod-liver oil, &c." Meat-peptone may also be used for any of the above purposes, although it is not so suitable as malto-peptone.—H. T. P.

An Improved Process for the Manufacture of Artificial Mineral Waters. H. Hubener, Berlin, Germany. Eng. Pat. 2245, February 7, 1891.

THIS invention has for its object the manufacture of artificial mineral waters free from atmospheric air, and containing mineral matters of a nature more beneficial than those usually found in waters of this class. For this purpose the following ingredients are dissolved in every 1,000 grms. of air-free distilled water:—

	Grms.
Phosphate of soda "free from air"...	0.73
Sulphate of soda free from air.....	1.20
Carbonate of lime	0.15

and a small quantity of citrate of soda according to taste. Preferably the solution is sterilised and rendered perfectly free from air by boiling; or the air may be removed by suction. The air-free water is finally led into a closed vessel containing carbonic acid, and from thence to a machine in which it is charged with carbonic acid at $2\frac{1}{2}$ atmospheres pressure, and bottled in the usual way.

—H. T. P.

Process and Apparatus for Sterilising Liquids. O. Imray. From "Calberla, Fitz und Consorten," Berlin, Germany. Eng. Pat. 2816, February 16, 1891.

THE patented process is designed to sterilise milk and similar liquids continuously and in large quantity, by means of an apparatus of which all the parts are permanently connected during the operation. A device is also patented for removing the objectionable flavour of milk that has been heated in order to sterilise it. The apparatus consists essentially of a pasteurising vessel of cylindrical form, and having the whole of the steam, water, and air pipes, as well as the agitator, suspended from the lid, so that they can be removed at one operation for cleaning. The vessel is connected with a set of four vessels provided similarly with a supply of water, air, and steam, which act as germinators, the object being to develop those spores that have resisted the action of the first pasteurising apparatus, which suffices to destroy fully-developed bacteria. The milk having passed through these vessels is again pasteurised in an apparatus similar to that already described, and then flows into the final germinators of form similar to the first set. Thus there are two sets of both pasteurising and germinating vessels, and in consequence the milk undergoes two distinct treatments of each kind. In the case of the condensation of the milk being required for foreign transport, an ordinary vacuum apparatus is provided immediately after the final germinators. The last portion of the plant is a sterilising apparatus similar to the pasteurising apparatus, but fitted in addition with a rose-like device by means of which cool sterilised air is forced through the milk with the view of improving its flavour. The air is sterilised in a separate vessel into which an antiseptic fluid, such as essential or volatile oil, is sprayed in a contrary direction to the flow of the in-coming air. The bottom of the vessel is provided with a liquid seal for drawing off the antiseptic liquid without opening the vessel. The cocks and joints of the apparatus are fitted with casings filled with antiseptic materials.—B. B.

An Improved Process for Preserving Milk. J. Oakhill and R. H. Leaker, Bristol. Eng. Pat. 2944, February 18, 1891.

FRESH milk, contained in hermetically-sealed vessels, is gradually heated in a water-bath up to a temperature (about 200° F.) sufficiently high to destroy or render inert the micro-organisms present in the milk. The bath is then allowed to cool down, and the milk is finally cooled to 32° F. by placing the containing vessel in cold water or in a refrigerator.

"Milk thus treated remains in a sound and unimpaired state while the vessel remains unopened."

Drawings of apparatus accompany the specification.

Improvements Relating to the Making-up or Packing of Baking Powders. W. P. Clotworthy, Baltimore, U.S.A. Eng. Pat. 18,491, October 27, 1891.

By this invention it is intended to avoid the rapid deterioration of baking powder, due to the gradual interaction of its acid and alkaline constituents during storage. For this purpose the acid and the alkaline carbonate or bicarbonate are packed in layers, a layer of starch or flour being placed between the two. Baking powders thus prepared will retain their aërating power for any length of time. It is convenient to make them up in packets containing sufficient for one pound of flour (see following abstract).—H. T. P.

Improvements Relating to the Making up or Packing of Baking Powders. W. P. Clotworthy, Baltimore, U.S.A. Eng. Pat. 18,499, October 27, 1891. (See preceding abstract, Eng. Pat. 18,491, 1891).

THE layer of starch separating the acid from the alkaline carbonate may be disposed with, the two constituents of the baking powder being simply packed consecutively in a suitable receptacle. The portions of acid and carbonate in immediate contact form a layer of neutral salt which effectually prevents further action.—H. T. P.

Improvements in Means for Preserving Meat, Fruits, and such like Perishable Articles in Store or in Transit. H. S. Elworthy, Sujampur, India. Eng. Pat. 19,817, November 16, 1891.

THE process consists in storing the meat, &c. to be preserved in a closed chamber charged with moist carbon dioxide or sulphur dioxide under pressure. The preservative influence of the gas employed may be increased by saturating it with some volatile antiseptic, such as cresote, which for this purpose is placed in the chamber in a dish, or sprinkled on a cloth, &c., or cotton wool, &c., soaked in the antiseptic may be placed in the gas inlet pipe. The carbon or sulphur dioxide is preferably employed in the compressed or liquefied state, a reducing valve being used to lower the pressure to the desired extent. Details of the necessary apparatus are given.—H. T. P.

Improvements in the Manufacture of Carbonated Waters. M. L. Orr, Blackrock, P. G. Hovenden, and J. Vass, Dublin. Eng. Pat. 19,927, November 17, 1891.

By means of this invention it is intended to more highly charge carbonated waters with carbonic acid. To this end the excess of carbonic acid, escaping through the automatic valve of the carbonating cylinder is passed into a strong

closed subsidiary tank containing the liquid to be carbonated. This tank is fitted with a valve made to open at a lower pressure than the valve on the carbonating cylinder, so that the air expelled from the water by the carbonic acid may readily escape. The liquid in the tank is maintained at a constant level by means of a floating ball which actuates either the inlet-tap or a water pump, which it throws in and out of gear. Any salts which it may be desired to add to the water are forced (in solution) into the tank by a second pump of suitable diameter. In operation, the water in the subsidiary tank becomes gradually charged with carbonic acid. It is then pumped into the carbonating cylinder and impregnated with a further quantity of gas in the usual way; and it is claimed that in this manner highly charged waters may be obtained at a comparatively low pressure.

—H. T. P.

Improved Method of and Appliances for Filling Sterilised Liquids into Vessels, and in Closing said Vessels Air-tight. H. D. Fitzpatrick. From G. H. Neuhass, J. F. H. Gronwald, and E. H. C. Oehlmann, Berlin, Germany. Eng. Pat. 20,086, November 19, 1891.

THE method patented consists in the use of an elastic rubber tube for filling the vessel intended to contain the sterilised liquid, which, after the vessel has been filled, can be drawn flat across the mouth, the stopper forced in, and the tube afterwards cut off. A separate elastic cover can be used instead of the end of the delivery tube, to avoid the gradual shortening of the latter which otherwise occurs. In order to prevent air leaking into the bottle after closure has been effected, the elastic tube may be tied up and cut off so as to form an elastic bag, which may be everted into the bottle and thus prevent the passage of any air to the liquid. Alterations in the external pressure are provided for by the expansion and contraction of the bag, and thus the formation of a space between the liquid and the stopper is avoided. The bag may be filled with a liquid not liable to change in contact with the air, and the stopper may be hollow to provide an additional reservoir of liquid. A hole-bored through the stopper allows the pressure of the atmosphere to be transmitted to the bag and its contents. Another form of the method described, consists in the attachment to the neck of the vessel to be filled, by means of washers and clamps, of a cylindrical cover with side tubulures for the introduction of the sterilised liquid, and provided with vertical plungers passing through stuffing boxes for inserting the stopper and wiring it down by any ordinary form of bow-fastening.—B. B.

An Improved Method of Preventing the Curdling of Albuminous Solutions. J. E. Alén, Gothenburg, Sweden. Eng. Pat. 20,419, November 24, 1891.

THIS invention relates to a method of preventing the curdling of samples of milk intended for analysis, and consists in adding to the milk a small quantity of a soluble chromate. 0.025 grm. of potassium bichromate per 100 cc. of milk suffices to preserve it at the ordinary temperature for 12 days, whilst 0.01 grm. per 100 cc. would probably prevent curdling for 24 hours. To preserve milk for 1—2 months, an addition of 0.1 to 0.2 grm. of the salt is necessary. A soluble compound of mercury may be employed instead of the chromate, or may be used in conjunction with the latter to increase the preservative action. Samples of milk collected during several days' working may be preserved by this process and finally united to form an average sample, thus avoiding the necessity of having each day's sample separately analysed.

—H. T. P.

An Improved Process of Manufacturing Kumyss Compounds or Kumyss Tablets. J. Carnrick, New York, U.S.A. Eng. Pat. 21,372, December 7, 1891.

THE object of this invention is to manufacture an artificial dry kumyss compound from which, by solution in water, an effervescent kumyss beverage may be readily prepared. To

this end, fresh milk, deprived of most of its fat, is subjected at 125° F. to the action of a digestive ferment, preferably pancreatine, for half an hour, or until 30 per cent. of the caseine has been digested and rendered soluble. The milk is then sterilised by heating to 190° F., and subsequently evaporated to dryness in a vacuum pan. During this operation sufficient cocoa-butter is added to replace the natural fat originally removed, and cane and milk sugars are also added in such proportions that the dry extract may contain 10 per cent. and 20 per cent. of them respectively. The dry residue is ground to a fine powder and mixed with sufficient bicarbonate of soda and citric acid to render it effervescent, lactic acid or a small quantity of a suitable ferment being also added to produce a further fermentation if desired. Finally, the mixture is moulded into tablets. These tablets when dissolved in water in a tightly-stoppered bottle yield liquid kumyss as a white opaque fluid "perfectly free from lumps or curds," and which, when the bottle is opened, forms "an agreeable effervescent, nutritious food-beverage adapted for the use of invalids and convalescents." If the bottled kumyss be kept for 2—4 days, fermentation sets in with the production of lactic acid, alcohol, and carbonic acid, whilst the caseine is rendered still more readily digestible.—H. T. P.

Improved Apparatus for Cooling Liquids. H. S. Elworthy, Sujanpur, India. Eng. Pat. 21,518, December 9, 1891.

THE apparatus for which the claim is made, and which is also applicable to the aerated water machine described in Eng. Pat. 19,815 of 1891, is illustrated by the accompanying diagrams.

Fig. 1.

Fig. 2.

APPARATUS FOR COOLING LIQUIDS.

The tank B contains the liquor which is to be cooled. Within it is placed the receptacle C containing brine, which

surrounds another vessel D, closed at the top and fitted with a central tube finishing with a nozzle at the bottom. The vessel D is further encircled by a small spiral tube *e'* which enters the vessel at its lower end but is free to the atmosphere at the top. On a connexion being established between the central tube *cd* and the bottle A containing compressed gas, and the valve O being opened, the gas escapes through the nozzle into the vessel D, where it expands and produces intense cold, the coiled pipe *e'* allowing it to escape to the atmosphere, and, on its way, to abstract heat from the brine.—B.

Physiological Research on Carbon Monoxide. N. Grehan. Compt. Rend. 1891, 113, 289—290.

THE author's experiments show that one part of carbon monoxide in 10,000 parts of air may be detected by aspirating the air through dog's blood and testing the respiratory capacity of the blood before and after the experiment. By passing 200 litres of air containing 20 cc. of carbon monoxide through 50 cc. of blood the respiratory capacity was found to decrease from 23.7 cc. to 23.0 cc., showing, according to the experiments of C. Bernard, that 0.7 cc. of carbon monoxide had replaced an equal volume of oxygen in the blood. When the air was passed through the blood under a pressure of 5 atmospheres, the respiratory capacity was reduced much more—from 23.7 cc. to 17.2 cc., corresponding to an absorption of 6.5 cc. of CO. By passing the air under pressure in this manner the delicacy of the test becomes considerably increased, whilst it is also shown that the absorption of the carbon monoxide by the hemoglobin of the blood is dependent upon the pressure and is proportional to the weight of carbon monoxide contained in a given volume of air, and not to the percentage of contained gas.—C. A. K.

PATENTS.

An Improved Method of and Apparatus for the Purification of Smoke in Chimneys. E. R. Salwey, Bristol. Eng. Pat. 4565, March 14, 1891.

A cage loosely filled with asbestos wool or other suitable non-inflammable material is placed in the upper part of the chimney for the purpose of removing sooty particles, &c., from the smoke, more particularly that arising from the domestic hearth. When necessary the cage is either removed for cleaning or it is burnt clean *in situ* by means of a gas jet.—D. A. L.

XIX.—PAPER, PASTEBOARD, Etc.

The Acid Action of Drawing Paper of Different Makes.
W. N. Hartley, F.R.S. Proc. Chem. Soc. 1892, No. 106,
19—22.

The author had experimented with various kinds of the best paper in use, both of old and recent manufacture, and had come to the conclusion that such papers were invariably acid, even those of the most excellent quality. The fact was accounted for as follows:—The fibre of which the paper is made is steeped in dilute sulphuric acid, and the subsequent washing with pure water does not entirely remove the acid from linen fibre, of which the best papers are made. He actually found nine linen to retain traces of acid after it had been steeped in frequently renewed pure distilled water for a period of three weeks. The acid seems to combine with the fibre, and the resulting compound is only slowly decomposed or dissolved by the action of water. Such linen gives a blue colour when an aqueous solution of iodine is dropped upon it. There was no intention to convey the idea that the paper contained free acid in such quantity that it could be easily removed by washing, or that it would affect litmus paper, which generally is not a sensitive agent. The samples of paper exhibited at the meeting were carefully tested in the following manner:—A pure and neutral solution of azolitmin prepared from litmus was allowed to drop upon the paper and soak into the fibres; the edges of the drops were then examined, and found to be red. The bulk of the liquid was then removed by a piece of the same paper, with the result that in every case a red spot was seen, which dried red. Another mode of testing was as follows:—A clear sable brush washed in distilled water was used for applying a wash of pure neutral azolitmin solution, as if it were a pigment, such washes turned red upon the paper.

Prof. Church, in his work on "The Chemistry of Paints and Painting," 290, published in 1890, remarks that he is unable to endorse author's statement that the best drawing papers have an acid action. He finds, in fact, that sized papers are generally neutral to test-papers, and that inferior papers are more often slightly alkaline than acid.

The papers examined by the author were all of the best quality, most of them being of Whatman's make. That no question may arise on this point, he has tested the samples named below in three ways: first, by dropping litmus solution upon the paper; secondly, by washing with a sable brush; thirdly, by steeping strips of paper in pure distilled warm water, and testing the water for acidity, and also for sulphates. The acid action was recognised by a pure litmus solution, by an ordinary laboratory preparation and by a carefully prepared solution of helianthin, though this last agent is not very sensitive.

The results are identical with those obtained on former occasions. The description of the samples and their actions is as follows:—

1. Whatman's hand-made paper, 96 lb., old make. Washes, acid; drops, acid; water, decidedly acid. Large precipitate with barium sulphate insoluble in dilute hydrochloric acid.

2. Whatman's double thick Imperial, 140 lb. Washes, acid; drops, acid; water, decidedly acid. Large precipitate of barium sulphate, as with No. 1.

3. Whatman's double elephant, hand-made. Washes, acid; drops, acid; water, strongly acid. Large precipitate of barium sulphate, as with No. 1.

4. Whatman's hand-made, 72 lb., 1887. Washes, acid; drops, acid; water, decidedly acid. Large precipitate of barium sulphate, as with No. 1.

5. Saunderson's hand-made. Washes, acid; drops, acid; water, decidedly acid.

6. Hollingworth's machine-made paper. Washes, barely acid; drops of strong litmus neutral in colour; water, very slightly acid, almost neutral.

7. Arnold's unbleached hand-made paper. Washes, acid.

No further tests for acidity were recorded.

It will be seen from these notes that there were good grounds for attributing an acid action to even the best of drawing papers. In other words, if a very sensitive solution of pure litmus be applied to paper in the same manner as a strong pigment, as for instance in delicate washes, the action is, in almost every case, distinctly acid; but if a drop of a strong solution be allowed to sink into the paper and dry up, its colour may be so slightly changed as to appear violet, leading to the inference that the paper is neutral. The strength of the solution of litmus, and the manner in which it is applied, must therefore be taken into account, because the quantity of the purple colouring matter in contact with the paper may be more than sufficient to overpower the red tint caused by the acid present in the moistened material. It is therefore extremely probable that there has been only an incomplete understanding as to the degree of acidity of the paper. Solutions of helianthin painted on the various samples of paper gave at first a pure yellow tint, which gradually changed to a colour intermediate between rose-colour and yellow. Very dilute solutions, washed on freely, showed after some minutes a pale rose-colour, mixed with a yellowish tinge. A sufficiency of acid yields a fine rose tint with such a solution. Hollingworth's paper did not show in any degree an acid action with helianthin, although it gave a slight indication with litmus.

The Acid Action of Drawing Papers. C. Beadle. Proc. Chem. Soc. 1892, No. 107, 34—35.

Prof. W. N. Hartley recently communicated a note on this subject (previous abstract) which raises questions of considerable technical importance. The fact of the "acidity" of papers need not be discussed, and Prof. Hartley's contention that an acid constituent in the paper has a serious effect on "water colours" applied to the paper the author is not in a position to criticise. He merely wishes to point out that Hartley is probably in error as to the cause of the acidity, which he takes to be a residue of sulphuric acid left in the "fibre" (rags) after the process of "souring" and washing.

The mill where the "Whatman" papers are made is situated at Maidstone, and the water used in the manufacture is the characteristically hard water of that district. The "souring" of the rags is followed by a long process of continuous washing in the "engine," and after some years' experience of paper making in the Kentish district the author is satisfied that no acid can survive this treatment.

On the other hand, the papers are sized with gelatin and alum and it is to the presence of the latter constituent that the "acidity" is, in his opinion, due. In a recent examination of one of these papers the author obtained, by treating with distilled water, an exhaust which showed "acidity" equal to 2.3 cc. normal H_2SO_4 per 100 grms. paper, using litmus as indicator in the titration, and yet this exhaust was basic to methyl orange. Sulphate of alumina, $Al_2(SO_4)_3$, being acid to methyl orange, the evidence is complete that the apparent "acidity" of the aqueous exhaust is due to the presence of a basic sulphate of alumina (this Journal, 1891, 202).

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Conversion of Gallic Acid and Tannic Acid into Benzoic Acid. C. E. Guignet. Compt. Rend. 1891, 113, 200—201.

A mixture of ammonia and zinc dust is heated in a flask fitted with cork and tube. So soon as the evolution of hydrogen is sufficiently regular a warm solution of gallic acid is added little by little. By keeping the temperature at

60° C. the gallic acid is completely converted after several hours. To extract the acid the mixture is boiled with potassium carbonate after the zinc has been precipitated as carbonate and the ammonia transformed into carbonate, evaporated to dryness, and taken up with alcohol, which dissolves the potassium benzoate. The same end may be attained by heating gallic acid with zinc and dilute sulphuric acid; in this case the benzoic acid is obtained in the form of yellowish insoluble particles. These are filtered off and washed free of zinc sulphate; the residue, consisting of benzoic acid and excess of zinc, may be treated with alcohol, or distilled directly. The sulphate of zinc solution contains also some benzoic acid, which may be separated as potassium benzoate by adding excess of potassium carbonate, evaporating to dryness, and extracting with alcohol. Tannic acid may be converted into benzoic acid under exactly similar conditions.

This reduction of gallic acid is in agreement with the synthesis by treating di-iodosalicylic acid with potash.

Catechu-tannic acid is likewise closely allied to benzoic acid. This tannin is intimately connected with catechin, which accompanies it, and gives the same derived products. Catechin dissolved in potash gives protocatechuic acid, which is one of the dioxybenzoic acids. The methods of reduction may thus very considerably facilitate the study of the tannins, such as the tannin of oak bark.—T. L. B.

New Crystalline Oxychlorides of Iron. G. Rousseau. *Compt. Rend.* 1891, **113**, 542—544.

A concentrated solution of ferric chloride, containing over 80 per cent. of Fe_2Cl_6 , kept for some time at a temperature between 160° and 220°, gives rise to a crystallised oxychloride of iron, $2\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6 \cdot 3\text{H}_2\text{O}$. This compound in contact with boiling water is gradually changed into a hydrate $\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, which is completely isomorphous with the oxychloride. The author has carried on the study of the decomposition of solutions of ferric chloride at temperatures higher than 220°. The solutions contained 85 to 90 per cent. of Fe_2Cl_6 , and were sealed in glass tubes with a fragment of marble. In the interval between 225 and 280° reddish-brown scales are deposited; their composition corresponds to that of the anhydrous oxychloride $\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6$. Between 300 and 340° brownish-black scales of a new oxychloride $3\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6$ are produced. These oxychlorides are only slightly soluble in dilute mineral acids. Heated in boiling water for 150 to 200 hours in presence of marble they lose all their chlorine, and are converted into brownish-red sesquioxide.—D. E. J.

On the Solution of Bismuth Chloride in Saturated Solutions of Common Salt and on Basic Salicylate of Bismuth. H. Gansse. *Compt. Rend.* 1891, **113**, 547—549.

The author has previously shown that ammonium chloride hinders the dissociating action of water upon salts of bismuth, and has now found that sodium chloride acts in the same way. Thus if dilute hydrochloric acid (about 1 to 4) is allowed to act upon bismuth oxide until no further solution takes place, it is always found that the amount of oxide dissolved is much smaller than (about one-half) that required to saturate the acid; in other words, a considerable portion of the acid is required to maintain the solution in equilibrium. If the solution is now saturated with common salt and again placed in contact with bismuth oxide it will dissolve a further quantity. The author finds that the total amount held in solution in the latter case is almost exactly that required for complete neutralisation of the acid present. He has applied this method to the production of basic salicylate of bismuth, which is prepared as follows:—35 grms. of bismuth oxide are dissolved in 40 cc. of concentrated hydrochloric acid; this solution is mixed with 500 cc. of a saturated solution of common salt; the free acid is then neutralised either by adding oxide or carbonate of bismuth, or by pouring in a saturated solution of sodium carbonate and chloride until the precipitate produced refuses to dissolve. 9 grms. of caustic soda and 22 grms. of salicylate of soda are introduced into another

500 cc. of solution of common salt: this solution is filtered and allowed to run into the first. The solution becomes violet in colour and a precipitate of salicylate of bismuth is formed according to the equation—

The mother-liquor is decanted off and the salt is washed with water slightly acidulated with nitric acid until the washings are colourless. The salt thus obtained is in the form of microscopic prisms. When heated it decomposes with loss of salicylic acid.—D. E. J.

The Action of Benzoic Acid on Turpentine. G. Bouchardat and J. Lafont. *Compt. Rend.* 1891, **113**, 551—553.

Benzoic acid appears to combine slowly in the cold with French turpentine; at 150°, taking equal weights of acid and turpentine, the action is rapid; after heating for 50 hours the change is complete. The treatment is best carried out in a copper vessel with a reversed condenser. Several products are obtained. Before proceeding to isolate them it is necessary to remove the uncombined acid by means of an alkaline solution. The product is distilled up to 200°—220°, the thermometer dipping into the liquid.

The portions which volatilise above 200° consist of *camphene*, which is solid, boiling at 157°, and *terpene* its liquid isomer, which boils at 175°—180°. Both have only a slight action on polarised light. About half the product distils above 220°. It partially decomposes on distillation, but if the pressure is reduced to 3 cm. it can be distilled at 190°—195°. The residue consists of polyterpenes (principally colophonium) volatilising at about 315°. This product, distilling in vacuo at about 190°, consists of an oily mixture of benzoic ethers of *camphenol* and *isocamphenol*. These benzoates are scarcely attacked by boiling aqueous solutions of the alkalis; on the other hand they can be saponified in the cold by an alcoholic solution of potash. The product after saponification should be washed and fractionated, the fractions being collected for intervals of 2·5°. The fractions distilling above 205° deposit, on standing at 15°, abundant crystals of levorotatory camphenol, mixed with a little dextro-rotatory isocamphenol. The portions distilling between 185° and 205° are dextro-rotatory, those above and below are levorotatory.—D. E. J.

The Preparation of Crystallised Hydroxylamine.

L. Crismer. *Bull. Soc. Chim.* 1891, **6**, 793—795.

Two methods are given for the preparation of this substance from zinc dihydroxylamine chloride $\text{ZnCl}_2(\text{NH}_2\text{OH})_2$.

1. The dry zinc salt (10 grms.) is distilled in vacuo with some organic base, preferably aniline (20 cc. of pure, recently distilled aniline), capable of displacing the hydroxylamine from the double salt. A strongly refracting liquid passes over at first; but towards the end of the distillation the drops crystallise as they enter the receiver, and soon the whole of the distillate sets to a mass of large, colourless plates. The solidification may be hastened by placing the receiver in ice. Finally, the crystals are transferred to a filtering tube, plugged with glass-wool, and washed free from adhering aniline with a small quantity of absolute ether. Moisture must be carefully excluded during the whole of the operation by means of calcium chloride tubes, &c. The hydroxylamine thus obtained possesses all the properties ascribed to that substance. It is soluble in water in all proportions; and the crystals on exposure to air attract moisture so rapidly that they liquefy and volatilise.

2. A current of dry ammonia gas (dried by KOH) is passed into a mixture of a few grms. of the zinc salt with 100 cc. of anhydrous ether, contained in a flask, moist air being carefully excluded. The zinc salt is decomposed, and swells up. The reaction being completed, the ether is decanted and distilled in vacuo. The crystalline residue left in the retort consists of pure hydroxylamine.—H. T. P.

Action of Hydriodic Acid on Cinchonine. G. Pami Monatsh. 1891, **12**, 582—588. (Compare Skraup, this Journal, 1891, 946, and Lippmann and Fleissner, *ibid*, 915).

CINCHONINE combines with 3 mols. of hydrogen iodide, forming a compound of the composition $C_{19}H_{23}N_3O(HI)_3$, which begins to decompose at 223°, and melts at 230°; when this salt is carefully treated with alcoholic ammonia at the ordinary temperature it is converted into an unstable base of the composition $C_{19}H_{23}N_3OI_2$, which melts at 187°—190°, but begins to decompose at about 175°. This base, which is named *dihydriodocinchonine*, forms a crystalline *nitrate*, $C_{19}H_{23}N_3OI_2, HNO_3$, and a crystalline *sulphate* ($C_{19}H_{23}N_3OI_2, H_2SO_4$); when it is boiled with an alcoholic solution of sodium ethoxide it yields cinchonine and a smaller quantity of a substance, the composition of which was not determined; when warmed with silver nitrate in dilute alcoholic solution, it is converted into cinchonine.—F. S. K.

Action of Hydriodic Acid on Cinchonine. E. Lippmann and F. Fleissner. Monatsh. 1891, **12**, 661—666. (Compare Pami, preceding abstract).

THE authors have repeated some of their experiments on the formation of dihydriodocinchonine, $C_{19}H_{23}N_3OI$, and have confirmed the results previously obtained. They have also prepared the dihydriodocinchonine described by Pami (*loc. cit.*) by a method similar to that employed by the latter; this compound is decomposed by ammonia in the cold, yielding hydriodocinchonine. When a mixture of molecular proportions of cinchonine trihydriodide (compare Pami, *loc. cit.*) and hydriodocinchonine is dissolved in hot alcohol, a substance, melting at 187°—190°, which seems to be identical with Pami's dihydriodocinchonine, is deposited on cooling.—F. S. K.

Dissociation in Dilute Solutions of Tartrates.
S. Sonnenthal. Monatsh. 1891, **12**, 603—619.

THE author has examined very dilute solutions of various acid and neutral salts of tartaric acid, in order to ascertain the influence of concentration on the rotatory power; the results of his investigations may be summed up as follows:—

(1.) Aqueous solutions of neutral, and of acid tartrates, undergo a change of condition when a certain degree of dilution is attained.

(2.) This change begins to take place in the case of solutions of the neutral tartrates at between 0.4 and 0.3 per cent., but in the case of solutions of the acid salts not until between 0.3 and 0.2 per cent.

(3.) The commencement, and the amount, of this change is dependent on the nature of the salt-forming metal or radicle; the greater the atomic weight of the metal, or the molecular weight of the radicle, the greater the concentration at which the change begins, and the greater also the departure from the normal condition.

(4.) The rapidity with which the change in condition takes place seems to be dependent solely upon the greater or less solubility of the salt in question.

It would seem from these results that this change in condition is a dissociation phenomenon, more especially because relatively large masses of water must be present in order to produce the change, and, further, because the larger the atomic weight of the metal the sooner the change commences.—F. S. K.

Behaviour of Quinidine and of Quinine towards Hydriodic Acid. A. Schubert and Z. H. Skraup. Monatsh. 1891, **12**, 667—690. (Compare this Journal, 1891, 946.)

Dihydriodoquinidinehydriodide, $C_{20}H_{26}N_2O_2I_2.HI$ is formed, together with dihydriodo-apoquinidine hydriodide (see below) when anhydrous quinine is warmed with hydriodic acid of sp. gr. 1.7; if quinidine is heated with concen-

trated hydriodic acid (sp. gr. 1.96) at 100° for three hours, dihydriodo-apoquinidine hydriodide is the sole product, whereas when the reaction is carried out at the ordinary temperature and in the dark only dihydriodoquinidine hydriodide is formed. The last-named salt crystallises in large yellow plates, melts at 230°, and is insoluble in potash; when treated with alcoholic ammonia at the ordinary temperature it is converted into dihydriodoquinidine $C_{20}H_{26}N_2O_2I_2$. This base melts at 218°—220°, decomposes at about 228°, and is only very sparingly soluble in alcohol, and almost insoluble in water; it forms a crystalline *ovalate* ($C_{20}H_{26}N_2O_2I_2, C_2H_5O$), and a crystalline *hydrochloride* $C_{20}H_{26}N_2O_2I_2, HCl$.

Dihydriodoapoquinidine hydriodide, $C_{19}H_{23}N_2O_2I_2.HI$, melts at about 252°, and is soluble in potash. *Dihydriodoapoquinidine*, $C_{19}H_{23}N_2O_2I_2$, melts at about the same temperature as dihydriodoquinidine, and forms a crystalline *hydrochloride*, $C_{19}H_{23}N_2O_2I_2, HCl$, and a crystalline *nitrate*, $C_{19}H_{23}N_2O_2I_2, HNO_3$.

A base of the composition $C_{20}H_{26}N_2O_2$, isomeric with quinidine, is obtained when dihydriodoquinidine hydriodide is warmed with silver nitrate in dilute alcoholic solution; it melts at 78°—79°, and dissolves in acids yielding solutions which show a blue fluorescence and which give a green colouration with chlorine and ammonia. When dihydriodoapoquinidine is treated in a similar manner, it yields a base of the composition $C_{19}H_{23}N_2O_2$. This substance melts at 157°, and its acid solutions, which show a very slight greenish fluorescence, give with chlorine and ammonia a green colouration; this base seems also to be produced when dihydriodo-apoquinidine hydriodide is heated with aniline at 100° for a long time.

By heating anhydrous quinine with hydriodic acid of sp. gr. 1.17 at 100°, the authors obtained a salt melting at 228°—230° with decomposition, and identical with the hydriodoquinine hydriodide, $C_{20}H_{26}N_2O_2, 3HI$, described by Lippmann and Fleissner (this Journal, 1891, 915). This substance seems to be a mixture of two salts, because it is decomposed by alcoholic ammonia at the ordinary temperature, yielding a mixture of two bases having the composition $C_{20}H_{26}N_2O_2I$ and $C_{20}H_{26}N_2O_2I_2$ respectively, the former being present in the larger quantity.

The base of the composition $C_{20}H_{26}N_2O_2I$ (*hydriodoquinine*) is readily soluble in alcohol, but only sparingly in ether, and melts at 155°—160° with decomposition; its solution in dilute sulphuric acid shows a blue fluorescence, and gives a brownish-yellow precipitate with chlorine and ammonia.

When quinine is heated with hydriodic acid of sp. gr. 1.96 methyl iodide is evolved, and a salt of the composition $C_{19}H_{23}N_2O_2, 3HI$ is produced; this compound melts at 236°—238°, is soluble in potash, and is decomposed by alcoholic ammonia at the ordinary temperature, yielding a mixture of two bases having the composition $C_{19}H_{23}N_2O_2I_2$ and $C_{19}H_{23}N_2O_2I$ respectively, of which the former is produced in by far the larger quantity. It would seem, therefore, that the original salt is a mixture of the hydriodides of these two bases.—F. S. K.

The Alkaloids of the Solanaceae. W. Schütte. Arch. Pharm. 1891, **229**, 492.

THE investigations have been undertaken in view of the opinion expressed by Scheerer that the root of *Atropa Belladonna* does not contain any atropine but only hyoscyamine (Chem. Zeit. Rep. 1891, **15**, 117). The author finds that the young and wild belladonna roots contain only hyoscyamine, whilst the older roots, both wild and cultivated, contain atropine in small quantity side by side with the hyoscyamine. The ripe berries of cultivated *Atropa belladonna nigra* contain both atropine and hyoscyamine, whilst the fruit of the wild plant contains atropine only. The ripe fruit of *Atropa belladonna lutea* contains no hyoscyamine, the atropine being associated with a base perhaps identical with atropamine (this Journal, 1891, 158). The unripe fruit of the wild deadly nightshade contains essentially hyoscyamine, together with a little

atropine. The leaves of both deadly nightshades contain both alkaloids, the atropine again being present in small quantity only. Both fresh and old seeds of *Datura stramonium* consist essentially of hyoscyamine, but also contain a little atropine and scopolamine. *Solanum tuberosum* contains betain, together with an alkaloid possessing a mydriatic action which has not been identified. A similar alkaloid also occurs in very small quantities in *Lycium barbarum*, *Solanum nigrum*, and in *Nicotiana tabacum*. In the seeds, leaves, and root of *Anisodus luridus* hyoscyamine alone occurs.—C. A. K.

β-Naphthol Benzoate, or "*Benzonaphthol*," a New Intestinal Antiseptic. Yvon and Berlioz. J. Pharm. Chim. 1891, 24, 479.

β-Naphthol salicylate or "*betol*" produces objectionable secondary reactions in the system when the kidneys are disordered, owing to the separation of salicylic acid that takes place. To remedy this defect in the drug the authors have replaced the salicylic acid in betol by benzoic acid. The resulting benzonaphthol is decomposed in the body into *β-naphthol*, which remains in the bowels, and benzoic acid, which is eliminated in the urine either as such or as hippuric acid. To prepare the benzoate, *β-naphthol* and benzoyl chloride are heated gently to 125° C., and afterwards to 170° C., the mixture being kept at the latter temperature for half an hour. The product of the reaction is purified by recrystallisation from 90 per cent. alcohol, or any excess of *β-naphthol* may be removed by washing with very dilute caustic soda at 50–60° C. Benzonaphthol ($C_{17}H_{13}(C_{10}H_7O_2)$) is almost insoluble in water, fairly soluble in alcohol, and readily so in chloroform; it melts at 110° C. The pure product should not be coloured blue by the addition of solid caustic potash to its solution in pure chloroform and then warming, nor should the alcoholic solution be reddened on the addition of nitric acid, and a few drops of acid mercuric nitrate.

Benzonaphthol can be taken in considerable doses without producing any toxic effect. For adults the dose recommended is 5 grms. per day, for children 2 grms.—C. A. K.

Corydaline. J. J. Dobbie and A. Lauder. Proc. Chem. Soc. 1892, 105, 13–14.

ANALYSIS of the alkaloid, as well as of its salts and derivatives, led Herm. Wicke (Annalen, 1886, 137, 274) to assign to corydaline the formula $C_{17}H_{19}NO_4$. The authors have purified samples by recrystallisation from a mixture of alcohol and ether, and have obtained the alkaloid in the form of flat, prismatic, colourless crystals, melting at 134.5°. In analysing it they obtained results irreconcilable with Wicke's formula, $C_{17}H_{19}NO_4$, and propose instead the formula $C_{22}H_{25}NO_4$.

On oxidation with potassium permanganate, corydaline yields a number of products which the authors are now engaged in investigating.

Limettin. W. A. Tilden. Proc. Chem. Soc. 1892, 107, 33–34.

LIMETTIN is the name given by the author to a crystalline substance deposited from the essential oil of the lime, originally described by him in conjunction with C. R. Beck (C.S. Trans., 1890, 323).

Further investigation of its properties shows that, instead of the formula $C_{16}H_{11}O_6$ first attributed to it, limettin has the composition expressed by the molecular formula $C_{11}H_{10}O_4$, which requires nearly the same percentages of carbon and hydrogen.

By the action of nitric acid it is converted into a nitro-derivative $C_{11}H_9(NO_2)O_4$, and by the action of bromine into a dibromo-derivative $C_{11}H_8Br_2O_4$, while chlorine converts it into a trichloro-compound $C_{11}H_7Cl_3O_4$. The dibromo-compound also exchanges the third atom of hydrogen for chlorine, giving $C_{11}H_6Br_2ClO_4$. Oxidising agents convert

limettin into acetic or oxalic acid without definite intermediate products. Potash fusion produces from it phloroglucol and acetic, but no other acid. Treatment with concentrated solution of hydrogen iodide causes the elimination of two methyl groups.

Sulphuric acid slightly diluted causes limettin to assimilate a molecule of water forming a phenolic compound of which the diacetate was prepared and analysed.

Limettin is not attacked by acetyl chloride, by phenylhydrazine or by sodium amalgam, and it gives no colouration with ferric chloride. It forms very pale yellow, thin prisms, which melt at 147.5°; it dissolves in alcohol, benzene, toluene, and acetic acid pretty freely, but scarcely in water or in light petroleum. Dilute solutions exhibit a beautiful violet fluorescence. It seems to have the constitution $C_6H_5(OCH_3)_2.C_5H_7O_2$.

Synthetical Carbolie Acid. H. W. Jayne. American J. of Pharm. December 1891.

It has been known for some years that carbolie acid (phenol) could be produced by numerous synthetical methods, but interest in the subject has been especially manifested recently on account of several firms, in response to the constant demand for purer preparations, having undertaken its manufacture on a commercial scale. Of the many reactions by which phenol can be produced, only two are, at present, commercially practical, both using pure benzene as the starting point.

The first or sulphate method is applicable to the preparation of all phenols, and has been used for some years, producing on an immense scale naphthol. In this method pure benzene, free from thiophene, is placed with about five times its weight of strongest commercial sulphuric acid (67° B.) in closed cast-iron pots provided with stirrers and lead coolers, and capable of being heated by a steam jacket. While the mixture is slowly stirred, the vessel is gently heated with steam in such a manner that the vapours of benzene which pass into the cooler are continually returned to the kettle. After a number of hours the reaction is finished, and the benzene not acted on is collected as it flows from the cooler. The crude benzenesulphonic acid, mixed with the excess of sulphuric acid used, is allowed to cool, and then diluted with water in a lead-lined tank. Slaked lime is added to the hot solution in sufficient quantity until it is faintly alkaline. This removes the excess of acid by forming calcium sulphate, which is then filtered off by means of a filter-press. The clear liquor containing calcium benzenesulphonate is treated with sufficient sodium carbonate to precipitate all the calcium as carbonate, which is removed by filtration, and the liquor is now evaporated to dryness, leaving the sodium benzenesulphonate as a white powder.

In a large cast-iron kettle heated by a coal fire, caustic soda is melted, and small portions of the dry sodium salt, prepared as above, are gradually added, and finally the whole is kept in quiet fusion for some time. The melt now contains sodium carbolate and sulphite, together with the large excess of caustic soda used—

It is ladled from the kettle into pans and allowed to cool, broken up, dissolved in water, and acidified with sulphuric or hydrochloric acid. The phenol thus liberated separates from the concentrated salt solution, and can be collected and distilled.

In melting the sodium benzenesulphonate with caustic soda, it is necessary in order to obtain a good yield to use a very large excess of the latter. A greater yield is obtained with caustic potash, and if as large a quantity as six parts are used to one of the soda or potash salt a nearly theoretical yield can be obtained, but as this would greatly increase the cost, caustic soda is used instead.

It has been proposed to treat the melt after dissolving in water with carbonic acid gas, which would liberate the phenol equally well as a stronger acid, and in addition would form carbonate of soda or potash, which together with the

sulphite already present could be converted into the hydrate by treating with lime, concentrated, and used for a second operation.

The second method is much simpler. A pure aniline oil, preferably that grade called aniline for blue, is dissolved in water in a lead-lined tank covered with a hood, and provided with stirrers and leaden steam coils. The solution is acidulated very strongly with sulphuric acid, and to the hot liquid a solution of commercial nitrite of soda is gradually added, phenol being at once formed.

In this reaction the sodium nitrite, in contact with the acid solution, liberates nitrous acid, which forms diazobenzene-sulphate with the aniline sulphate—

but as the solution is hot it at once decomposes into phenol with evolution of nitrogen—

Neither of these synthetical methods can at the present time compete in price with the extraction of carbolic acid directly from the coal-tar oils.

A good grade of crystal acid can be purchased abroad in large quantities at this time at about 11 cents per pound, while the pure benzene used in the first method is worth at the English refineries about 14 cents per pound, and aniline oil about 20 cents, without taking into consideration the other expensive chemicals necessary to carry out the reaction.

When the synthetical acid was first placed upon the market it excited much interest, and purchasers were willing to pay the high price it commanded, believing that they were getting a much purer article than could be produced by the ordinary methods. This interest has, however, considerably abated since the acid has been found to redden just as easily as the best commercial grades.

It could scarcely be expected that an acid obtained by either of the complex reactions just described would not be contaminated by products formed by side reactions in the process. In its preparation by the sulphonate method, sulphur compounds (thiophenols, &c.) are likely to be formed; and its manufacture from a substance like aniline, which so readily produces colouring matters, could scarcely be carried out without at the same time forming bodies which at once or later under the influence of light and air would discolour it.

In addition, commercially pure benzene or aniline oil always contain small quantities of, respectively, toluene or toluidine. These bodies being submitted to the same treatment as their homologues give cresol. It is true that this body would be present only in minute quantities, but sufficient to reduce the melting point of the resulting phenol.

Lunge has shown that the addition of 1.3 per cent. of cresol to pure phenol reduces the melting point 8° to $31\frac{1}{2}^\circ$, and in the preparation of a high grade carbolic acid a difference of a part of a degree is of great importance.

"Forty degrees acid" is at present a commercial article sold at excessively low prices, and if a small part of the attention and labour which is used in producing a synthetical acid was expended in the further purification of this 40° acid, without doubt just as pure if not a purer article could be produced direct from tar oils and at a very much lower cost.

Chemical Study of the German and Turkish Otto of Roses. U. Eckart. Archiv. des Pharm. **229**, 355; Monit. Scient. November 1891, 1145—1153.

THE centre of production for this essential oil is Roumelia, 120 villages on the confines of Kesanlik possessing 2,500 stills, and furnishing from 1,900 to 2,500 kilos. per annum. No one knows precisely the date at which this industry was commenced, but it is believed to have been somewhere about the 17th century. For the preparation of the essential oil, the *Rosa Damascena f. trigintipalata* is principally cultivated, a cultured red variety of *Rosa gallica* and of *Rosa centifolia* richer in essence than the white variety.

The fresh petals are introduced into alembics of tinned copper with an addition of twice their weight of water. The contents of the vessel are then submitted to distillation, which is stopped when half the water has passed over. The product is then submitted to renewed distillation, receiving the sixth part of the liquid, which is let stand for two days. The supernatant essential oil is separated by means of small funnels of tin, and preserved in jars of tinned copper containing from 500 to 5,000 grms. each.

1,000 kilos. of fresh flowers yield about 160 to 400 grms. of essential oil. In recent years the firm of Schimmel and Co., of Leipsic, have cultivated the *R. centifolia major*, and have obtained by the distillation of 23,000 kilos. of fresh roses, 4 kilos. 500 grms. of essential oil. This product has in part served for the investigation to be described, along with another quantity of essential oil from Kesanlik which had had separated from it its stearoptene.

The Crude Essence.—The German essential oil obtained in the harvest of 1890, possesses at the ordinary temperature the consistence of butter, has a light green colour from chlorophyll, and melts at 27° . The odour is powerful, and recalls to some extent that of mint. This essence is finer than the Turkish product, and is composed of stearoptene and a liquid oil. It has no action on litmus paper moistened with alcohol, is easily soluble in ether and chloroform, but with difficulty in alcohol and glacial acetic acid. The Turkish essential oil solidifies at the ordinary temperatures, and melts at 17° to 22° . The melting point varies more or less with the extent of stearoptene, and this content is independent of the climate. The specific gravity of this oil oscillates between 0.87 and 0.89. The other properties approach very closely those of the German oil.

Separation of the Stearoptene.—The German essential oil is distilled and about 5 per cent. of the product is collected from 79° to 100° . The residue distilled in vacuo gives a fresh portion of liquid, whilst the stearoptene does not pass over. This process was replaced by the following, which, however, does not yield the products distilling below 100° . The oil is dissolved in five times its weight of alcohol at from 70° to 80° , the solution is cooled to 0° , agitating meanwhile. The stearoptene is separated by filtration, and washed with cold alcohol. The alcoholic solution is evaporated in vacuo, and an oil is thus obtained almost completely free from stearoptene. By this treatment it is possible to obtain:—

(1.) A product distilling below 100° , obtained by the method first specified.

(2.) Elaeoptene, remaining portion of the liquid product.

(4.) Stearoptene.

The principal part of the essence, that also which is aromatic, is the elaeoptene.

Product passing over below 100° .—This product, 5 per cent. of the essential oil, consists of ethylic alcohol.

Properties of the Oil separated from the Stearoptene.—*Physical Properties.*—This portion of the German essential oil is coloured a light green and has an odour like that of mint, a specific gravity of 0.891 at 11.5° , and the power of rotating the plane of polarised light to the left. It easily dissolves in ether, alcohol, chloroform, bisulphide of carbon, benzene, petroleum spirit, and glacial acetic acid. The Turkish oil freed from stearoptene possesses an odour strongly resembling that of mint, is yellowish in colour and has a specific gravity of 0.8804 to 0.8813 at 15° . According to the polariscope of Wild, it turns the plane of polarised light to the left 5.4° for a length of 200 mm. As regards solubility it behaves like the elaeoptene of the German oil.

Chemical Properties.—This oil only contains carbon, oxygen, and hydrogen. It is neutral and without action on ferric chloride. Potash and an ammoniacal solution of nitrate of silver are equally without action on the substance. It does not combine with hydroxylamine. Consequently it neither possesses the phenolic, aldehydic, or cetic functions.

Submitted to distillation in portions of 20 to 30 grms., this oil passes over from 110° to 120° under a pressure of 12 mm. (It is necessary to avoid the use of more of the product for distillation than that mentioned, for a portion becomes transformed into a non-volatile substance.) Analysis gave numbers corresponding to the formula $C_{10}H_{15}O$.

The compound $C_{10}H_{16}O$, which Markownikoff found in the oil of Bulgarian roses, contains 76.92 per cent. C, 12.82 per cent. H, whereas the author found 11.40 to 11.70 per cent. H (this Journal, 1891, 63).

The eleoptene does not contain terpenes, and this extract of the Turkish essential oil behaves like that found in the German oil. Thus they show the following physical constants:—

Specific Gravity.	Temperature.	Boiling Point.	Index of Refraction.	Molecular Refraction.	Dispersion.	Rotatory Power.
THE ELEOPTENE OF THE GERMAN ESSENCE.						
.. .. 0.8837	15	216	1.4775	49.28	12.5	2.8
	18	..	1.4719	49.28	12.5	2.8

THE ELEOPTENE OF TURKISH ESSENCE.						
2nd fraction. 0.8789	18	216	1.4719	48.97	12.0	2.7
3rd fraction. 0.8782	18	217	1.4718	48.98	11.7	2.7
4th fraction	18	217	1.4725	48.98	11.1	2.7

The author gives the substance the name of *Rhodinol*, and various compounds of this body are now described. By heating rhodinol for three hours from 180° to 120° in a sealed tube, with lime or an alkali, it is decomposed so as to yield small quantities of valerianic acid, acetic acid, and formic acid.

Stearoptene.—Rose oil contains from 20 to 68 per cent. of this substance, which, according to Flückiger, crystallises in the hexagonal system, boils at 32.5° and distils at about 350° , though not without decomposition. Its formula expresses a carbide $C_{16}H_{34}$, and on oxidation by nitric acid, succinic and oxalic acids are produced along with other acids. The carbide thus appears to belong to the fatty series. From the stearoptene of the Turkish oil two carbides were isolated, one of which melted at 23° and the other at 40° , the German oil yielding under the same conditions a carbide melting at 22° and another the melting point of which lies between 40° and 41° .

Thus, the conclusion is arrived at that stearoptene from rose oils is a mixture of different homologous hydrocarbons.

The author confirms the fact of the existence of two kinds of stearoptene in the rose oils. The oils obtained in cold countries are richer in stearoptene than those of hot countries, but it must be added that the amount of stearoptene varies in the same region with the time of the year. The melting point of the rose oil is shown to depend upon the amount of stearoptene present, that the melting point of this body is not always the same, and that it is generally lower as the percentage of the stearoptene increases. The research shows that the Turkish and German oils are composed of three substances: Ethylic alcohol, eleoptene, and stearoptene. The most important constituent is eleoptene, or *rhodinol* $C_{10}H_{16}O$, which belongs to the series of alcohols, $C_nH_{2n-2}O$. It is further shown that rhodinol belongs to the methane series. Thus rose oil can be classed amongst the rare essential oils which contain bodies rich in carbon, and in which the chain is a closed one. Rhodinol is a primary alcohol. Its molecular refraction and absorption for bromine point to two ethylene links in its chain. Its optical properties indicate that it contains an atom of asymmetric carbon. The production of terpenes points to the position in the ring of the methyl and propyl groups. The formula thus derived explains easily the transformation of rhodinol first into limonene and then into dipentene—

The constitution of *Geraniol*, an isomeride which behaves like rhodinol, is, according to Semmler—

(this Journal, 1890, 889 and 1145). According to the author, the difference between the two isomerides lies in the positions of the groups of methyl and propyl, in those of the double links, and in the nature of the asymmetric carbon.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photography in Colours. Labatut. Compt. Rend. 1891 113, 126—129.

THE author has employed Lippmann's method for photographing in natural colours (this Journal, 1891, 483), to show that when colour sensitizers are employed the maximum effect of the acting light corresponds exactly to absorption spectra of the dyes used. The colours experimented with were Cyanine and Victoria green. In both cases the maximum effect was coincident with the light absorbed by the transparent and sensitised emulsion used, whilst as in the previous experiments the resulting plates after development showed complementary colours when viewed by direct and by reflected light respectively. The due interpretation of this result in relation to the wave theory of light is discussed in the paper. Since the colours on the sensitive plate, obtained when any colour sensitizer is used indicate the portion of the light rays absorbed by the plate, it is unnecessary to examine such sensitizers spectroscopically in order to ascertain the limits of their action.—C. A. K.

The Action of Light on Silver Chloride. A. Béchamp. Bull. Soc. Chim. 1891, 6, 836—840.

THE recent work of Guntz in this direction (this Journal, 1892, 179) has induced the author to recapitulate some experiments made by himself in 1833.

Pure silver chloride was exposed under water to the action of light for four days, the water being frequently changed. The supernatant liquid soon after the commencement of the experiment gave a precipitate with silver nitrate, and readily decolourised a solution of indigo. At the same time no gas was apparently disengaged from the

chloride, and the odour of the water was somewhat different from that of chlorine. Evidently an oxygen compound of chlorine had been formed. The blackened chloride was afterwards collected and dried. When fused it did not diminish appreciably in weight, proving the absence of an oxychloride, and on cooling separated into two layers, the one being yellow, transparent, and horny, the other black and porous. From the loss of weight undergone by the silver chloride during exposure to light, the amount of silver-subchloride, Ag_2Cl , present (assuming it to have been formed) was deduced and found to be equal to rather more than one-sixth of the total chloride taken; and the author remarks that so far as he can remember the relative bulks of the horny and porous layers above mentioned were in the same ratio. Referring to Guntz's discovery, that silver chloride which has been heated in absence of light becomes reducible by the oxalate developer, the author remarks that by an investigation of the action of solar light deprived of its heat rays, on silver chloride, an explanation might possibly be found for the varying influence of light, transmitted by coloured and uncoloured screens, on silver chloride.—H. T. P.

Quantitative Estimation of Silver and Gold by Means of Hydroxylamine Hydrochloride. A. Leiner. *Monatsh.* 1891, 12, 639—641.

See under XXIII., page 271.

PATENT.

Improvements in or Relating to Magnesium Flash Lights. R. Hadden, London. From F. H. F. Engel, Hamburg, Germany. Eng. Pat. 7487, April 30, 1891.

IN this improved apparatus the magnesium reservoir is mounted in such a manner that it can be turned on the blowing tube and so be brought into an inverted position over cavities, provided for receiving the magnesium powder, along the upper part of the blowing tube; these then become charged and the reservoir is turned back again; any superfluous powder being wiped from off the blowing tube back into the reservoir by lateral strips of packing. A puff of air into the blowing tube projects the powder into burning gas jets placed above, but with this apparatus the cavities can be quickly refilled by repeating the above operations.

XXII.—EXPLOSIVES, MATCHES, Etc.

PATENTS.

Improvements in the Manufacture of Explosive Substances. H. E. Newton, London. From A. Nobel, Paris, France. Eng. Pat. 5331, April 16, 1886. (Second Edition.)

This invention describes "explosives composed of a nitrate, chlorate, or perchlorate of the metallic bases intimately mixed with nitroglycerol or equivalent explosive matter, but without the addition of combustible matter."—W. M.

Improvements in the Manufacture or Production of Gunpowder or like Explosives. J. Y. Johnson, London. From the "Dynamite Actiengesellschaft Nobel," Vienna, Austria. Eng. Pat. 6128, April 9, 1891.

A SMOKELESS powder is made by mixing 70–99 parts of nitro-starch with 1–30 parts of di- or tri-nitrobenzene and compressing the powder to a suitable degree. The pressure employed imparts a density to the grains which "gives the lowest possible pressure of gas on combustion."—W. M.

Improvements in and Relating to High Explosives for Use in Mining and for Military and other Purposes. J. M. Pollard, Washington, U.S.A. Eng. Pat. 20,418, November 24, 1891.

THIS invention consists essentially in the manner of mixing chlorates or nitrates and sulphur together. Sulphur is first added to melted paraffin so that each particle becomes coated with the hydrocarbon, then the chlorate or nitrate is added and the incorporation continued. The mass may now be pressed into cartridges, or if the explosive be desired in the form of grains it is granulated while hot and allowed to cool gradually, so that each particle may retain its coating of paraffin and thus become waterproofed.—W. M.

Improvements in Railway Fog Signal Detonators. A. Ruston and E. Beadle, London. Eng. Pat. 21,879, December 15, 1891.

IN this signal the base is formed with a recess in which the clip for attaching it to the rail is secured so that the surfaces of the base and clip lie flush on the rail. The top is also formed with a circular recess for holding the percussion caps in position.—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Composition of Glass suitable for Chemical Apparatus. R. Weber. *Zeits. f. angew. Chem.* 1891, 662—665.

THE author, continuing the investigation he has been engaged in for years, has examined some more specimens of glass with the following results:—

Glass.	Percentage of					Ratio.		
	SiO_2	Al_2O_3	Fe_2O_3	$\text{CaO}(\text{MgO})$	K_2O	Na_2O	$\text{SiO}_2:\text{CaO}:$	$\left(\frac{\text{K}_2\text{O}}{\text{Na}_2\text{O}}\right)$

Glass A was a fragment of a finely graduated burette, it had become rough both in and outside, glittering flakes dropped from it when it was gently heated, and on boiling for a short time with water it yielded a solution strongly alkaline to ordinary indicators. Glass B was from a boiling flask; this flask when left filled with water for about four weeks became coated inside with a gelatinous deposit, which was developed again by a second treatment. In the two treatments the flask, 0.8 litre capacity, lost 0.162 gm. in weight. From the analytical data it is presumed that this glass must have been prepared from a mixture of 100 parts of sand, 14 parts of calc spar, 14.5 parts of potash, and 28 parts of soda, a mixture which cannot yield a proper glass. Both this and the first glass are absolutely unfit for

chemical apparatus. Glass C is a sample of similar inferior glass examined 10 years or so ago. Glasses D and E are from flasks about 100 cc. capacity, of Bohemian manufacture. These were only slightly affected by prolonged exposure to the air or to the fumes of hydrochloric acid, and when water was boiled in them continuously for six hours they lost 0.012 gm. in weight. Glass F is a similar glass examined 10 years or so ago. Glass G is an example of excellent window glass, glass H of French glass used in the manufacture of Fresnel's lighthouse lenses, both characterised by their high resistance towards ordinary deteriorating agents. Glass I is a sample of "Hohl" glass, from which articles of great durability have been manufactured. Glass J is a similar good glass examined in 1879. It seems that what is required is more lime and less alkali in glasses for chemical purposes, and the author is of opinion that much might be done in improving matters in this direction without fear of increasing the cost of production on account of decreased fusibility. Glass K is an example of a glass which the author has obtained for some years; it resists the action of air and acid fumes well, and loses only very slightly in weight on boiling with water or dilute acid; thus a 100 cc. flask of this glass only lost 0.008 after boiling water in it six hours continuously. This glass is decidedly less readily fusible, but nevertheless does not present any special difficulty to be overcome in its manufacture.—D. A. L.

A Mixer and Divider for Ore Samples, and small Sampling Machine. H. L. Bridgman. Eng. and Mining J. 1892, 275.

This apparatus (Fig. 1) entirely obviates the tedious and

Fig. 1.

frequently inaccurate methods—usually with oil cloth and spatula—now in general use, for mixing and dividing the ground samples of ore, matte, slag, and other similar material. An experience of several months has shown a very decided improvement in accuracy, speed, and general convenience over the old way.

The operation is as follows:—The ground material is introduced into the large covered funnel (mixer), the outlet being first closed by thumb or finger, as may be most convenient. Funnel and contents are then well shaken for a few minutes, and then, with open outlet, passed to and fro over the set of distributing funnels (divider) and bottles, as shown. With very finely ground or very light material the flow may be assisted by a slight shaking or tapping with the hand. The little skill necessary is readily acquired.

The mixer will also be found very useful for the prompt and thorough mixing of crucible assay charges and all other work of similar character.

To test the efficiency of the mixer, a lot of 6 assay tons of litharge, 3 assay tons of soda and $\frac{3}{4}$ assay ton of argols was taken, well shaken, divided by weight into three lots of $3\frac{1}{4}$ assay tons each, and these charges fused separately in crucibles. The resulting lead buttons weighed 53.436 grms., 53.416 grms., and 53.398 grms. respectively.

The ore sampling machine is shown in Fig. 2. Its particular field of usefulness is the quick and certain cutting down of the miscellaneous small samples (from 5 lb. to 500 lb. in weight) that are constantly being received by all assay offices. It is applicable for anything from the fines

assay pulp to crushed material of one-half inch or more in size. It is a very decided improvement over any of the

Fig. 2.

present methods of quartering, or cutting down with sample shovel or tin sampler.

In operation, the material is fed either by hand or (with large lots) from a suitably supported bucket into the funnel F, the divider D being first set in rotation by hand, clockwork, or any convenient power. The divider gives eight cuts to the revolution, four being delivered to the funnel 1, and four to the receptacle 2; that is, with uniform flow and speed, cutting the material in half. The divider may easily run 100 revolutions per minute, giving in that time 800 cuts, a very much greater distribution and division than can be secured in any other way. The rejected sample passes down the outlet to O₂, both into suitable vessels. The retained portion, should it be too large, may be cut again and again until of suitable size. The operation is very accurate and very rapid, being about as fast as the material will flow through a 1-in. spout.

INORGANIC CHEMISTRY.— QUANTITATIVE.

The Direct Determination of Aluminium in Iron and Steel. T. M. Drown and A. G. McKenna. Technology Quarterly, 1891, **4**, 220—227.

The unsatisfactory nature of most methods for the direct determination of aluminium in presence of iron and phosphoric acid, and the sharpness with which the two latter can be estimated, have led chemists to rely mainly upon processes in which the aluminium is obtained by difference. But in examining modern alloys which may contain only a fraction per cent. of aluminium, nothing short of its direct determination can be satisfactory.

The authors have found that it is possible to remove iron by electrolysis from its acid solution using a current that in no way affects the aluminium present. The essential condition of success is the use (as proposed for other purposes by Dr. Wolcott Gibbs) of mercury as a cathode, the iron forming an amalgam with the mercury as fast as it is deposited from solution. Preliminary experiments made to test the completeness of the deposition of iron showed an apparent loss notwithstanding that the iron was completely removed from solution. This was found to be due

to the volatilisation of mercury on drying before weighing. To free the mercury completely from moisture it is only necessary to heat it for about two minutes at a temperature of 100°C ., and in this time the loss is very small. It is, however, advisable, in cases where the process is used to determine iron, to have a blank beaker in the circuit containing only mercury and dilute sulphuric acid, and to add any loss which may be found in this beaker to the amount found in others in the series. The best conditions for the rapid precipitation of the iron are a strong current (about 2 amperes or 20 cc. of electrolytic gas a minute), a nearly neutral solution of small bulk, a large amount of mercury (not less than 50 times the weight of the iron to be precipitated), and a large anode of platinum. The mercury cathode is brought into the circuit by means of a platinum wire enclosed and fused into one end of a glass tube, which passes through the liquid. It is of advantage to pour mercury into this tube to the depth of an inch, in order to weight it and make the connexion with the mercury cathode more stable. 10 grms. of iron can be precipitated in 10 to 15 hours. The iron amalgam may contain as much as 10 per cent. of iron. After long exposure to air, the iron separates out as a black powder, which may be removed by agitation with water. The mercury may be purified by filtration through chamois leather, and then passing air through it.

Secondly, the authors find that under the foregoing conditions manganese in solution is partly reduced to the metallic state (forming an alloy with the mercury) and partly oxidised to the dioxide which coats the platinum anode.

Thirdly, as to the influence of phosphoric acid on the deposition of iron. Duplicate experiments made with and without addition of phosphoric acid (hydrogen di-sodium phosphate) showed that its presence did not affect the deposition of the iron, and further, that the phosphoric acid in solution could afterwards be accurately determined by precipitation with magnesium mixture.

Fourthly, as to the separation of iron and aluminium solutions containing known amounts of both (as sulphates) were electrolysed, and, after the iron had been deposited and estimated, the aluminium was precipitated by ammonia. The results were entirely satisfactory.

Finally, the following process is recommended in the examination of iron or steel. Dissolve 5 to 10 grms. of the sample in sulphuric acid, evaporate until white fumes of sulphuric anhydride begin to come off, add water and heat until all the iron is in solution, filter off silica and carbon, and wash with water acidulated with sulphuric acid. Make the filtrate nearly neutral with ammonia, and add to the beaker in which the electrolysis is to be made about 100 times as much mercury as the weight of iron or steel taken. The bulk of the solution should be from 300 to 500 cc. Pass a current of about two amperes over night. In the morning test for iron, and, if necessary, continue the electrolysis after adding nearly enough ammonia to neutralise the acid set free. Finally, remove the solution from the beaker with a pipette while the current is still passing. When as much has been removed as possible without breaking the current, add water, and continue the operation until the acid has been so far diluted that there is no danger of dissolving iron from the mercury. Take the anode out and wash the mercury. After filtering (to remove any flakes of MnO_2) add sodium phosphate in excess, and 10 grms. of sodium acetate. Make nearly neutral with ammonia and boil for 40 minutes. The precipitate of aluminium phosphate is then filtered off, ignited, and weighed.—D. E. J.

On a New Hydrate of Copper, and on the Preparation of Pure Nitrogen. A. Le Due. *Compt. Rend.* 1891, **113**, 71–72.

By carefully watching what happens in the preparation of pure nitrogen by means of copper, the author has been led to discover a new compound of copper with hydrogen. This new compound has nothing in common with the compound discovered by Wurtz, which is formed in the cold and disappears entirely at about 60° . This, on the other hand,

is formed at a dull red heat by direct union of its elements, and shows only traces of dissociation at a bright red heat. It is, therefore, analogous to the alkaline hydrides discovered by Troost and Hauteville.

In preparing pure nitrogen (in order to determine its density), the author as usual passed pure dry air through a tube of Bohemian glass containing copper turnings heated to a red heat. He found it was important to carry out this operation at a somewhat dull red heat; also to have near the further end of the tube about 10 cm. of oxidised turnings. Several experiments in which the tube was raised to incandescence, showed that these oxidised turnings at the end were completely reduced, and the nitrogen formed in these experiments had (like Regnault's) too low a density. The explanation lay in the fact that the copper used had first been oxidised, and then reduced in a current of hydrogen in order to give it a clean surface. This was shown to be the case by the following experiment.

The tube containing the copper filings was heated to a bright red heat in the middle and to 300° towards the ends; a current of hydrogen was passed for two hours, and the copper was then allowed to cool in the gas. In the parts of the tube which had been heated to a dull red heat there was formed a large quantity of a substance of a beautiful hyacinth-red colour, partly on the metal itself and partly on the top of the tube. A current of carbonic acid was afterwards passed through the cold tube, and the gas on leaving was completely absorbed by potash; the tube was then gradually raised to incandescence. The gas now ceased to be completely absorbed, and in a quarter of an hour over 20 cc. of gas was collected, which proved to be hydrogen mixed with a small quantity of carbonic oxide, formed by the reducing action of hydrogen upon carbonic acid.

The author is convinced that the hydrogen in the above substance is really combined with the copper, and not merely absorbed by it.—D. E. J.

New Method of Examining Chrome Yellows. M. Lachaud and C. Lepierre. *Bull. Soc. Chim.* 1891, **6**, 235–237.

The authors have shown that chromate of lead on treatment with dilute solutions of potash become decomposed, according to the equation—

On this reaction the following analytical process is based. Two grms. of the lead chromate are well shaken in a flask with 20 cc. of binormal potash solution (112 grms. of KHO per litre). The mixture is diluted with distilled water, and the solution is decanted or filtered from the residual basic chromate. The excess of potash in the solution is determined by titration with sulphuric acid in presence of phenolphthalein, the latter part of the titration being performed with very dilute acid in order to observe the transition point more exactly. From the amount of potash neutralised by the chromic acid extracted from the original pigment, the total amount of normal lead chromate can be calculated. The process is recommended for simplicity and rapidity.—G. H. B.

The Action of Light on Silver Chloride. A. Béchamp. *Bull. Soc. Chim.* 1891, **6**, 836–840.

See under XXI., page 266.

On the Colorimetric Determination of Iron by Means of the Sulphocyanate and other Coloured Compounds of the Metal. J. Ribau. *Bull. Soc. Chim.* 1821, **6**, 916–920.

A METHOD of estimating small quantities of iron (especially in blood) has been proposed, which is based on transforming it into the sulphocyanate and comparing in a colorimeter the solution thus obtained with a standard solution containing a known quantity of the sulphocyanate. The author has examined the accuracy of the method by means of a Duboseq colorimeter. In using this instrument (and all

others of the same type) a certain assumption is made. Calling the amounts of the colouring matter contained in the two solutions to be compared p and p_1 , and the depths of two columns of the respective solutions which appear of the same colour e and e_1 , then it is usually assumed that—

$$\frac{p}{p_1} = \frac{e_1}{e}$$

In order to test the reliability of the method it is sufficient to see whether experiment shows that this relation is true.

A series of solutions of ferric chloride was prepared containing regularly decreasing amounts, p_0, p_1, p_2, p_3 , &c. of iron, so that—

$$p_1 = \frac{p_0}{2}, p_2 = \frac{p_1}{2}, \text{ \&c.}$$

To the original solution (from which the others were prepared by successive dilutions with water) a large excess of ammonium sulphocyanate was added in order to diminish the dissociation which the dilution with water might be expected to produce. The first solution (p_0) contained 0.0001 grm. of iron per cc.; the fifth (p_4) contained 0.0000063 grm. per cc. The solutions were compared in pairs and the depths (e_0, e_1, e_2 , &c.) required to produce equality of tint were noted. The results show a wide divergence from the values required by the relation—

$$\frac{p}{p_1} = \frac{e_1}{e}$$

(Thus, e.g., in comparing p_1 and p_4 , the ratio between e_1 and e_4 was found to be 14.8, whereas according to the theory it should be = 8.) This divergence is most marked when the solutions compared are of very unequal concentration. The discrepancy is due to progressive dissociation of the sulphocyanate by water. The method is therefore unreliable excepting when the two solutions to be compared are of the same composition and strength; and in practical colorimetry it is difficult, if not impossible, to fulfil these conditions.

The author has endeavoured to obtain better results by transforming the iron salt into acetate (both neutral and acid), and also into alkaline tartrate of iron, but without success. The neutral acetate decomposes in the cold in about 24 hours, depositing a basic acetate; and the addition of acetic acid scarcely mends matters. Dilute solutions of the alkaline tartrate lose their colour spontaneously in the light.—D. E. J.

The Composition of the Atmosphere: a New Gravimetric Method for ascertaining the Same. A. Ledue. Compt. Rend. 1891, 113, 129—132.

THE method adopted for ascertaining the gravimetric composition of the air is a modification of that proposed by Brunner, and consists in absorbing the oxygen contained in a known weight of air by means of phosphorus and weighing the residual nitrogen. Full details are given of the precautions taken to avoid all possible sources of error. The method is considered more exact than that of Dumas and Boussingault inasmuch as any error arising from the occlusion of hydrogen by the copper used in their method is avoided. Two analyses made at intervals of six days gave 23.244 and 23.208 per cent. of oxygen by weight, whilst Dumas and Boussingault found 23 per cent. of oxygen. This corresponds to 21.02 per cent. of oxygen by volume, a result agreeing with that obtained by the author from a comparison of the specific gravities of oxygen and nitrogen.—C. A. K.

α -Orthostannic Acid. G. Neumann. Monatsh. 1891, 12, 515—523.

THE author attempted to isolate germanium from the mother-liquors of commercial tin-salt, but without success; in the course of these experiments a considerable quantity of stannic chloride was prepared, and the boiling point of

this compound was found to be 114°, under a pressure of 760 mm. When a solution of stannic chloride containing a large quantity of ammonium sulphate is treated with a small quantity of an aqueous solution of hydrogen sulphide, a white precipitate is produced; this precipitate has, when air-dried, the composition $\text{SnO}_2 \cdot 2\text{H}_2\text{O}$, or $\text{Sn}(\text{OH})_4$, and is readily soluble in hydrochloric acid, so that it must be regarded as the hydrate of α -stannic acid. The same compound is obtained when a solution of stannic chloride is treated with an alkaline sulphate alone.—F. S. K.

Estimations in Alkaline Solution by aid of Hydrogen Peroxide. P. Jannasch and R. Niederhöflich. Ber. 1891, 24, 3945—3947. (See also this Journal, 1891, 659 and 1037.)

Separation of Zinc and Manganese.—The mixture of sulphates dissolved in 50 cc. of water in a platinum dish had added to it 10 cc. of a 10 per cent. solution of cyanide of potassium, and then 10 cc. of a 25 per cent. caustic potash solution; the whole was stirred until the precipitate was almost completely dissolved. The manganese was now precipitated with 50—60 cc. of hydrogen peroxide solution. The whole was heated for a quarter of an hour on the water-bath, and then filtered. The filtrate was saturated with hydrochloric acid on account of the nitrate of soda contained in the hydrogen peroxide, taken to dryness in a porcelain dish and heated to 110°—115°; the zinc was then precipitated in hydrochloric acid solution of the residue so obtained (silica being filtered off) with sodium carbonate and determined as oxide.

Since it is extremely difficult to remove all the potash from the manganese precipitate, it is advisable to re-dissolve in dilute nitric acid in presence of a small quantity of oxalic acid, and re-precipitate with hydrogen peroxide in ammoniacal solution.

It is mentioned that copper, in slightly ammoniacal solution, containing only small quantities of ammonia salts, is precipitated quantitatively by excess of hydrogen peroxide, and methods for the separation of copper and zinc, and also of copper and nickel, are in progress.—T. L. B.

The Estimation of the Inorganic Constituents of Raw Sugars. Alberti and Hempel. Zeits. Rübenzucker Ind. 1891, 27, 85—91.

See page 273.

Calculation of Slag Components. G. Murray. Eng. and Mining J. 1892, 281.

FROM a given set of ores which may be made into combinations such that there may be a division into three or more classes, in No. 1 metallic basic, No. 2 earthy basic, No. 3 acid, it is required to take of each such quantities as combined will give a mixture containing its components in desired proportion.

Let the proposed mixture be such that there shall be a , FeO metallic bases, b , CaO earthy bases, and c , SiO_2 acid components, the whole = 100 lb., so that the letters may express percentages: from this we have—

$$\text{Total FeO} = \frac{a}{c} \text{ SiO}_2 \text{ and } \frac{a}{b} \text{ CaO}$$

Take an ordinary example: Let the composition of required slag be 40 per cent. FeO, 20 per cent. CaO, 40 per cent. SiO_2 , in the sense above taken, No. (1) as above, 30 per cent. FeO, 5 per cent. CaO, 20 per cent. SiO_2 ; No. 2, 3 per cent. FeO, 50 per cent. CaO, 4 per cent. SiO_2 ; No. 3, 6 per cent. FeO, 2 per cent. CaO, 60 per cent. SiO_2 , weight of charge to be 1,000 lb.

Denote quantity of No. 1 by x , of No. 2 by y , take 100 lb. of No. 3.

Making the first term of an equation regarding FeO components, the second siliceous, we have—

$$0.30x + 6 + 0.03y = (0.50y + 0.05x + 2) \frac{a}{b} \cdot \frac{a}{b} = 2.$$

$$x = 4.85y - 10$$

$$0.30x + 6 + 0.03y = (0.20x + 0.04y + 60) \frac{a}{c} \cdot \frac{a}{c} = 1.$$

$$x = 540 + 0.1y = 4.85y - 10$$

$$4.75y = 550, \quad y = 118$$

$$x + y + \text{No. 3 ore} = 770$$

$$1,000 \div 770 = 1.3$$

$$118 \times 1.3 = 152; 552 \times 1.3 = 717; 100 \times 1.3 = 130; \text{total, } 1,000.$$

Amounts of FeO, CaO, SiO₂ contained in the above are respectively 227, 227, and 114, which relate to each other as required. The total is partly equal to the weight of slag in charge = 568 lb.

Were the quantities of FeO, CaO, SiO₂ in the generally constant quantity of coke used in place of those in No. 3 ore, the amounts of x, y deducted from 1,000, we should have the difference only to obtain in x, y , and No. 3 ore. On finding these and adding likes to likes, we have the amounts of the components in proportion required.

In practice, the above is not used in its entirety, small percentages of some elements being discarded, and in cases of very constant ore simple factors taking its place altogether.

The Estimation of Oxygen Dissolved in Water.

M. A. Adams. Proc. Chem. Soc. 105, 1—2.

THE author describes an apparatus in which the estimation of oxygen in water by Schützenberger's method may be carried out so as entirely to avoid the loss of oxygen, or diffusion or its entry. The essential feature is a cylindrical laboratory vessel about 350 cc. in capacity, 20 cm. long, and 5 cm. in diameter, provided with four small lateral tubulures midway from the closed ends. By means of these it is attached to two burettes, one containing the indigo carmine, the other hyposulphite solution, and also to a mercury reservoir and to a Y-tube, one branch of which is connected with a supply of the water to be examined, the other serving as an outlet for the water. The tubes are all controlled by pinchcocks. The water and the liquids for titration are sucked into the vessel by lowering the mercury reservoir, and are subsequently discharged by raising it again; the tubes passing into the vessel from the burettes are provided with india-rubber valves which prevent either reflux or diffusion taking place into the burettes.

The author then refers to the peculiar irregular manner in which the action is known to take place, and describes his own observations, giving the results both of experiments made in the manner directed by Schützenberger and in the indirect manner recommended by Roseoe and Lunt (this Journal, 1889, 729—732). From the results he concludes that in estimating oxygen by the Schützenberger process, the result obtained is liable to differ according to the rate at which the determination is effected, it being always higher when the titration is quickly performed.

Quantitative Estimation of Silver and Gold by Means of Hydroxylamine Hydrochloride. A. Lainer. Monatsh. 1891, 12, 639—641.

HYDROXYLAMINE hydrochloride, in presence of potash, is eminently suitable as a reagent for the quantitative determination of silver in silver nitrate, silver sodium thiosulphate, and silver potassium cyanide, and also for the complete reduction of chloride, bromide, and iodide of silver. Special experiments showed that the presence of organic acids, such as citric acid, does not prevent the precipitation of silver by hydroxylamine hydrochloride and potash. For separating silver from other metals, such as copper, for

example, it is first precipitated as chloride, and the washed precipitate reduced to metal by boiling it with an aqueous solution of hydroxylamine hydrochloride and potash.

Hydroxylamine hydrochloride alone precipitates gold from a solution of auric chloride in the cold, but on warming reduction takes place much more readily; this reaction may be very conveniently employed for the separation of gold from solutions of the chlorides of the alkalis and alkaline earths. In presence of potassium cyanide, gold is not precipitated from a solution of auric chloride on addition of hydroxylamine hydrochloride and potash, but it is completely precipitated from a solution of auric chloride containing sodium thiosulphate.

The above methods may be suitably employed for the recovery of silver and gold from photographic residues, commercial "reducing salt" being used instead of pure hydroxylamine hydrochloride. —F. S. K.

ORGANIC CHEMISTRY.—QUALITATIVE.

The Qualitative Reactions of Vegetable Lubricating Oils.

Holde. Mitt. könig. techn. Versuchs. 1891, 294—302.

THE author has investigated various reactions for the identification of various lubricating oils and the detection of their commonest impurities.

(a.) *Rape Oil*.—The detection of rape oil in such lubricating oils as olive oil, has been alleged to be possible by means of the sulphur which it, in common with other oils of the *cruciferae*, is said to contain. The usual method for this purpose consists in saponifying the oil and testing the product with a lead or silver salt. According to Schädler, however, cold pressed rape oil is free from sulphur, while Benedikt states that other oils that have been extracted by carbon disulphide, contain sulphur. Schweissinger failed to find sulphur in a large number of samples of genuine rape oil, a result in accordance with the author's experience. Schneider's method for detecting as little as 2 per cent. of rape oil in olive oil, which consists in dissolving one volume of the oil in two volumes of ether, and shaking the solution with 20 to 30 drops of a saturated alcoholic solution of silver nitrate, was found quite unreliable. The method proposed by Villavechia and Fabris, consisting in treating 10 cc. of the oil, previously saponified, with 2 cc. with a solution of silver nitrate and 10 cc. of dilute nitric acid, also proved unreliable, as the dark ring which is supposed to form between the two layers into which the liquid divides, appeared as readily with olive oil as with rape oil.

(b.) *Cotton-Seed Oil*.—Of the various forms of the Bechi test, which is too well known to need description, that devised by Milliau alone proved of value. Five per cent. of cotton-seed oil gave a chocolate-brown coloration, while pure rape oil and olive oil yielded only a yellow solution. The author confirms the statement of Dieterich (Hefenberger Annalen, 1890, 2) that cotton-seed oil, after being heated, may fail to give the reaction. One of the two samples examined gave a comparatively feeble coloration after it had been heated to 240° C., while the other yielded no perceptible result. The process proposed by Hirschsohn, which depends on the production of a red coloration with gold chloride in chloroformic solution, was also tried and condemned. The same remark applies to the use of nitric acid of sp. gr. 1.37, which is supposed to give a coffee-brown coloration. By shaking 1—2 cc. of the oil with an equal volume of nitric acid of sp. gr. 1.41 somewhat better results were obtained. The coloration was red-brown in the case of pure cotton-seed oil, and dirty yellow with pure olive oil, becoming brownish on standing. Refined rape oil gave a brown coloration. 20 per cent. of cotton-seed oil could be detected in olive oil, but 10 per cent. was not recognisable with certainty. The method has therefore a certain utility as a preliminary test. The tests proposed by Peters of warming equal volumes of the oil and acid together, and observing the colour of the solidified product, proved valueless.

(c.) *Sesame Oil*.—The well-known sugar test was found to be of value. The author carries it out by shaking about 2 cc. of hydrochloric acid of sp. gr. 1.19 with a pinch of powdered sugar, adding about double the volume of oil and again shaking. 0.5 per cent. to 1 per cent. can be thus detected. Pure olive oil, rape oil, and hemp oil gave only a yellowish colouration. The colouration should be observed immediately after the separation of the acid, as a solution of sugar in hydrochloric acid itself becomes reddish-brown on standing. Grace Calvert's method depending on the use of a mixture of nitric and sulphuric acid gave unsatisfactory results.

(d.) *Drying Oils*.—The method proposed by Benedikt, which consists in immersing a clean copper wire in a mixture of 2 cc. of nitric acid and 5 cc. of the oil to be tested, and stirring with a glass rod, proved ineffective when tried with linseed oil, no pink colouration of the wire being observed. With regard to hemp oil, Benedikt's method of treatment with hydrochloric acid of sp. gr. 1.19 or with nitric acid sp. gr. 1.18, which are said to give a green colour, and the test with a mixture of sulphuric acid and nitric acid mentioned by the same chemist, proved too uncertain for useful application.

(e.) *Brull's Reaction for Seed Oils*.—This reaction, which consists in warming 10 cc. of the oil to be tested with 0.1 of the grm. of powdered albumen and 2 cc. of nitric acid, which was stated to be of general applicability, was also found to be useless for the detection of seed oil in olive oil.

(f.) *Fish Oils*.—The reaction for the detection of fish oils by means of syrupy phosphoric acid has been already found valueless by Schädler and Grittner.

(g.) *Mineral Oils*.—The method already described by the author (Mittheilungen, 1890, 22) was further tested. It was found that in the presence of only small proportions of mineral oil (0.5 to 2 per cent.) the turbidity which first appears on the addition of water sometimes disappears on dilution, the mineral oil being dissolved in the soapy liquid.

(h.) *Rosin Oil*.—The method given in the Mittheilungen 1890, 19 (this Journal, 1890, 419), for the detection of rosin oil by means of sulphuric acid of sp. gr. 1.624, suffices for the examination of olive and rape oil. Morawsky's reaction (this Journal, 1889, 372) is also available in the absence of rosin. (Compare this Journal, 1891, 661.)

It appears from these results that qualitative reactions for the detection of adulterants in oils are of very limited utility, seeing that those tried the sugar test for sesame oil was the only one of undoubted reliability. This is not surprising when the fact that the reactions probably depend on unessential constituents of the oils is considered.—B. B.

On some Colour Reactions of the Carbohydrates. G. Bertrand. Bull. Soc. Chim. 1891, 6, 259–261.

WHEN a glucose is gently heated with concentrated hydrochloric acid containing a small quantity of phloroglucol a yellow colour is developed which passes rapidly to orange red. Ultimately a dirty red precipitate forms and the solution becomes partially decolourised. The reaction proceeds in the cold, but requires several hours for completion. Analogous reactions have been described by various authors, who have also employed orcinol and α -naphthol instead of phloroglucol; but the author considers that erroneous interpretations were given to the reactions, and instances the fact that Wiesner considered a violet colouration given by gum arabic with hydrochloric acid and orcinol to be due to the presence of a diastase. The author finds that the red colouration is given by this reaction with all the glucoses and substances furnishing glucose by hydration, but it is always necessary to use the concentrated acid, as dilution diminishes the number of substances susceptible of the reaction. Many of the phenols can be substituted for phloroglucol, and the employment of orcinol is the more instructive, as the colouration varies with the molecular condensation of the sugar to be examined; thus the colour is violet-blue with arabinose and xylose of the

five carbon atom class and orange-red with glucoses containing six carbon atoms. The author believes these reactions are attributable to certain furfural derivatives which are produced under the conditions of the experiment. The following colour reactions were obtained with orcinol and hydrochloric acid:—

1. Orange-red solution: glucose (by Soxhlet's method), glucose (from cellulose), galactose, mannose, levulose, sorbin, saccharose, lactose, maltose, melizitose, strechyoze, trehalose, isodulcite, glycogen, inulin, levulin, potato starch, rice starch, dextrin, achroo-dextrin, amygdaline, salicin, hesperidin.

2. Violet-blue solution: arabinose, xylose, cherry-tree gum, and other natural gums. Gum arabic and gum senegal give a violet-red colour.

3. No colouration: xylite, sorbite, duleite, mannite, perseite, inosite, pinito, bergénite, saccharin (of Peligot).
—G. H. B.

ORGANIC CHEMISTRY.—QUANTITATIVE.

The Detection of Saccharine. D. Vitali. L'Orosi 14, 109.

THREE different methods are given. In each case the saccharine is first isolated in the usual way and then tested for by one of the methods.

1. The substance is heated in a tube with three to four times its volume of slaked lime. Ammonia, calcium carbonate, calcium sulphate, and phenol are thereby formed. The latter, condensing in the colder parts of the tube, may be detected by a new colour test devised by the author. A few crystals of potassium chlorate are carefully added to a few cc. of concentrated sulphuric acid. A drop of this placed on a porcelain tile, and touched with a glass rod which has been moistened with the distilled product, produces when phenol is present a green colour, which changes to an intense blue.

2. When the substance is treated with concentrated sulphuric acid, benzoic acid is produced.

3. By heating with caustic soda, ammonia, salicylic acid, and sulphuric acid are produced.—J. C. C.

On Graphites. W. Luzi. Ber. 1891, 24, 4085–4095.

IT has been known for a considerable time that graphite puffs up when boiled for a lengthened period with concentrated sulphuric acid, then washed, dried, and ignited. The following reagents and mixtures of reagents have been used by various authors to produce the result, viz., concentrated sulphuric acid, a mixture of the same with concentrated nitric acid, a mixture of sulphuric acid with potassium bichromate, and a mixture of sulphuric acid with potassium chlorate. The present author finds concentrated nitric acid to act perfectly well alone; a mixture of sulphuric acid and potassium permanganate is also recommended. A quicker method, however, is to moisten the graphite on platinum foil with fuming nitric acid and then to heat to redness in the Bunsen flame. In this manner, by taking pieces of graphite of the size of peas, products may be obtained on which the structure of the formation is easily examined. These transformed pieces of graphite float on water, alcohol, and ether for weeks, and evacuation of the flask in which pieces were floating on water did not produce a sinking of the particles. A low-power microscope reveals the crystalline nature of the inner surfaces. This shortened method of treating graphite has resulted in a revelation of the fact that two classes of natural graphites exist, the members of the one class showing the puffing up with the treatment mentioned, the members of the other class showing no puffing up whatever.

Belonging to the first class are:—

Graphite from Ticonderoga, New York.

Ceylon graphite.

Norwegian graphite.

Graphite from Quebec.

Belonging to the second group are:—

Graphites from Passau, Siberia, New Mexico, Saxony, The Fichtelgebirge, and also "electric" graphite.

The author, conceiving the idea that there might be a difference in constitution between the two classes, made analyses of members of each class, but no essential difference in composition could be detected, and it would seem that two different modifications of carbon are here in question.—T. L. B.

A Method for the Alkalimetric Estimation of Phenol. R. Bader. *Zeits. Anal. Chem.* 1892, **31**, 58—60.

THE author has found that phenol in solution in water may be titrated with normal caustic soda, using as an indicator an alcoholic solution of symmetrical trinitrobenzene. This solution is made by dissolving as much trinitrobenzene (melting point 122°) as will lie on the point of a knife in 50 cc. of absolute alcohol and filtering; this solution has a slight yellow tinge and is acted upon by light, so it is best to prepare fresh solution from time to time. Not more than 2—3 drops must be used for each titration, and excess of alkali gives a reddish-yellow colouration. The results from this method are from $\frac{1}{4}$ to $\frac{1}{2}$ per cent. too high. The author gives several examples. As regards the application of the method to the titration of the homologues of phenol with ortho- and meta-cresol, the results are somewhat unsafe, whilst para-cresol gives at once a troublesome yellow colour with caustic soda. The author thinks the method would give good results with catechol and its isomerides.—J. C. C.

New Method for the Determination of Phenol. L. Carre. *Compt. Rend.* 1891, **113**, 139—141.

THE method consists in converting the phenol into picric acid, and then determining the quantity of the acid formed colorimetrically. The solution to be tested should be dilute; if strong it must be diluted to 10 times its original strength. 25 cc. of the liquid are placed in a small flask containing 5 cc. of nitric acid, and the mixture heated on the water-bath for 1—2 hours. The colouration at the end of the heating is compared with that given by solutions of phenol of known strength heated with the same quantity of nitric acid for exactly the same length of time. The method is rendered more accurate by adding 20 cc. of caustic soda solution after the heating and making up the solutions, both tests and standards, to 50 cc. In this case the solution must be filtered if necessary. In presence of small quantities of alcohol the heating on the water-bath must be continued for a sufficient length of time to volatilise the alcohol; if larger quantities are present the solution must be diluted first so as to prevent the formation of nitrous ether. If the phenol is impure it must be heated with the nitric acid until all tarry matters are destroyed. Two results given show the accuracy of the method.

—C. A. K.

The Testing of Inks. *Zeits. Anal. Chem.* 1892, **31**, 116—120.

A NORMAL ink is first prepared by dissolving 23.4 grms. of tannin and 7.7 grms. of crystallised gallic acid in water at 50°C ., and adding to it a solution of .6 grms. of gum arabic, 10 grms. of hydrochloric acid containing 2.5 grms. of HCl, a solution of 30 grms. of sulphate of iron, and 1 gm. of carbolic acid; the whole is diluted to 1 litre and allowed to stand for four days and the clear solution poured off. To this normal ink colouring matter is added to get the required tint. The ink to be tested having stood for three days is uncorked and 50 cc. is taken out from the centre of the liquid and filtered through a small fine filter-paper; 25 cc. of the filtrate are placed in a cylindrical vessel, the neck is closed loosely with filter-paper, and the liquid is allowed to stand for some time in diffused light and in contact with air free from ammonia and acid; if after 14 days there is a deposit on the walls of the vessel the ink is unsatisfactory.

In order to test the darkening qualities of the ink a sheet of the best white writing paper is stretched on a frame and placed at an angle of 45° , then a little of the unfiltered ink is allowed to run down the surface from a glass tube and

form a streak on the paper. Another streak of the first ink is formed in the same way by the side of the second and both are allowed to dry; then if they compare favourably both inks are diluted with an equal volume of water and fresh streaks are made, allowed to dry, and compared. Further, the paper may be cut into strips across the streaks and treated with water, 85 per cent. alcohol and 50 per cent. alcohol for two days, after drying they are again compared.

To test the fluidity the ink is allowed to flow from an oval spreader and the width of the streak measured. The tendency to blot may be observed in the first test. The stickiness is tested by putting bits of paper on the dried ink or by the hand.—J. C. C.

The Estimation of the Inorganic Constituents of Raw Sugars. Alberti and Hempel. *Zeits. Rubenzucker Ind.* 1891, **27**, 85—91.

IN practice, the ash of sugars is usually determined by the "sulphate" process, one-tenth being deducted from the weight of the sulphated ash, to allow for the increase due to the conversion of carbonates, &c., into sulphates. The authors point out that the results thus obtained are liable to serious errors, and are not even comparable amongst themselves, owing to the variable composition of sugar ash, and to the fact that mechanically introduced impurities, such as sand, are often present. Apart from this consideration, however, it is now becoming generally recognised that the organic non-sugars influence to a far greater extent than the mineral constituents of any given raw sugar, the production of uncrystallisable molasses during refining. The non-sugars are usually estimated by difference (100—ash, —water, —cane sugar); and the authors contend that the numbers thus obtained are always too low, because the ash, even when directly determined (without previous sulphation) contains something (CO_2) not present as such in the original sugar. The following process is recommended in order to overcome this difficulty. 6—7 grms. of coarsely powdered quartz-sand are ignited in a platinum dish, and after cooling, the whole is weighed. 5 grms. of sugar (in the case of molasses, 3 grms.) are then added and well mixed with the sand by stirring with a platinum wire. The dish and contents are subsequently ignited in a platinum muffle in the usual way. By this means the carbon dioxide is completely expelled from the ash, whilst the sulphates and chlorides originally present are not appreciably decomposed. The weight of ash found, therefore, accurately represents the total mineral matter present in the sugar. A large number of duplicate ash determinations made by the "sulphate" and "sand" processes, as well as a series of complete analyses of sugars are given, showing the variations in the percentages of organic non-sugars caused by adopting either the one or the other ash result.—H. T. P.

On the Estimation of Sugars by Ost's Copper Solution. M. Schmoeger. *Zeits. Rubenzucker Ind.* 1892, **28**, 23—27.

THE author, in general, confirms the advantages over Fehling's solution claimed by Ost for his cupric potassium carbonate solution (this Journal, 1890, 825 and 1160; 1891, 858). In the case of dextrose and invert sugar the agreement between duplicate determinations is very good, and the results are practically identical with those of Ost. With milk-sugar the results are not quite so satisfactory, and in this case the use of Fehling's solution is to be preferred. Ost's solution is, however, particularly to be recommended for the estimation of small quantities of invert sugar in presence of much cane sugar, since the latter has only a very slight reducing action on the reagent. The weaker solution (3.6 grms. of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ per litre) is most suitable for the purpose. There are, however, several drawbacks to the use of Ost's solution. In presence of calcium salts the precipitated cuprous oxide will contain calcium carbonate. According to the author this difficulty may be got over by precipitating the lime with potassium oxalate, and after filtration using the clear

filtrate for analysis. Another disadvantage is that Ost's stronger solution when boiled with water or a sugar solution, deposits a brown film of cupric oxide on the side of the beaker. This film ordinarily weighs from 1—2 mgrms. The weaker solution gives no such deposit even on prolonged boiling. As regards the keeping qualities of the reagent, the author finds that the stronger solution after several months (sometimes weeks) storage in closed bottles deposits a distinct blue sediment consisting chiefly of a copper silicate, the silicic acid being derived from the glass which was strongly attacked. Ost's weaker solution remains unaltered under similar conditions.—H. T. P.

The Melting Points of Mixtures of Hydrocarbons.

ANALYTICAL AND SCIENTIFIC NOTES.

The Flow of Water, Petroleum, and Mineral Oil through Tubes.

H. Merczyng. Chem. Zeit. Rep. 1891, **15**, 223.

WHEN liquids flow through tubes two cases occur. If the liquid passes through capillary tubes, the fluidity of the body is calculated after Poiseuille's formula—

$$Q = \frac{\pi a}{8k} r^4$$

a being equal to the working pressure (the difference between the pressure at the beginning and end of tube), r = radius, k = constant of friction. This formula only holds good for tubes up to 1 mm. diameter, and where the length exceeds the diameter 40 times. In practice, to determine the fluidity of any liquid, being given the diameter of the tube and the pressure used, the formula—

$$Q = \gamma \sqrt{i d^3}$$

can be made use of where γ is an experimentally-obtained constant, which alters in a certain proportion to the rate of outflow of the liquid.

The temperature of the liquid on flowing out is of importance, as it alters the viscosity and friction constant, greatly decreasing the latter as the temperature rises. In practical work the rise of temperature due to movement of the liquid through tubes in the case of water, petroleum, and mineral oil may be neglected in the calculation. Krussel's experiments gave the following results, one kilo. of liquid flowing through the tube per second:—

Temp.	Water.				Petroleum.			
	Under a Pressure of Kilos.				Spec. Grav. 0.823. Under Pressure of Kilos.			
	0.70	1.40	2.11	2.81	0.70	1.40	2.11	2.81

Magnesium Nitride.

V. Merz. Ber. **24**, 3940—3944.

MAGNESIUM nitride, Mg_3N_2 , may be prepared in the form of a light yellow mass, becoming darker on heating, by passing pure dry nitrogen over magnesium powder, previously carefully dried, and strongly heated by a compound Bunsen burner. It may, however, be obtained more readily and at a lower temperature by substituting ammonium for nitrogen. The gas must be dried with great thoroughness by passage through long absorption tubes of caustic potash and lime, and the powdered magnesium must be equally free from moisture. Hydrogen is evolved in almost the calculated amount, and the magnesium nitride obtained corresponds to the formula Mg_3N_2 , sundry samples prepared by the author containing nearly 27 per cent. of nitrogen as against 28 per cent. demanded by theory. A small proportion of the magnesium attacks the glass of the combustion tube, and therefore absorbs no nitrogen. Only traces of hydrogen were recognised in the author's preparation.—B. B.

A Mode of Formation of Sulphide Minerals.

E. Chuard. Compt. Rend. 1890, **113**, 194—196.

THE work of Daubrée (Compt. Rend. 1875, **80**, 461) illustrates the manner of formation of a number of sulphide minerals, such as galena, pyrites, tetrahedrite, by the aid of sulphuretted waters, but such a method of formation cannot well have been universal, and examination is here entered into of objects of the bronze period found in the Swiss lake districts. Bronze objects embedded actually in the mud have been found to be coated very thinly with a substance which proves to contain:—

	Per Cent.
Sulphur.....	27.09
Tin.....	5.07
Iron.....	31.05
Copper.....	33.97

—T. L. B.

Physiological Research on Carbon Monoxide.

N. Grehant. Compt. Rend. 1891, **113**, 289—290.

See under XVIII.—B., page 260.

On Certain Capillary Phenomena and the Spheroidal State.

E. Gossart. Compt. Rend. 1891, **113**, 537—540.

THE author has measured by means of Le Chatelier's pyrometer the minimum temperature at which a plate will support a liquid in the spheroidal state. In the case of

platinum, which cannot be satisfactorily polished, he has always found that Bontigny's values are correct. But on well-polished gold and silver he has found globules remain in the spheroidal state decidedly below their point of ebullition (e.g. water on a plate at 80°).

He also finds that durable spheroids (in all respects like those of Leidenfrost) can be obtained by introducing into a liquid, lying on a polished support, drops of another liquid of greater density and superficial tension. Such is the case with mercury in water, alcohol, saline solutions, &c., on polished gold. The gold remains unattracted for about half an hour, and there is no electrical contact between the plate and the drop. The mobility of the spheroid shows that it is in a condition different from that of a drop of mercury in free air.—D. E. J.

New Books.

REACTIONEN. Eine Auswahl in Pharmaceutischer Hinsicht-wichtiger Präparate der organischen Chemie, in ihrem Verhalten zu der gebräuchlichsten Reagentien. Von F. A. FLÜCKIGER. 1892. Berlin: R. Gaertner's Verlagsbuchhandlung, Hermann Heyfelder, Schönebergerstrasse, 26, S.W. London: H. Grevel & Co., 33, King Street, Covent Garden.

A SMALL compact work on the Qualitative Determination of the more important pharmaceutical preparations and compounds of Organic Chemistry. It contains, besides the author's Preface, a List and definition of the most commonly employed reagents, the temperature being 15° C. The text covers 163 pages, and at the close is an Alphabetical Index of substances treated of. The book is bound in cloth. Price 4s.

Besides the reactions for the vegeto-alkaloids, the newer coal-tar medicaments are fully treated, and we note amongst these the following:—Antifebrin, Antipyrine, Betol, Phenol, Quinoline, Cocaïn, Cumarin, Eegonine, Exalgin, Guaiacol (wood-tar), Isonaphthol, Iodol, Methacetin, Methylacetanilide, Naphthalene, Naphthol, Phenacetin, Phenyl-dihydroquinazoline, Phenyl-dimethylpyrazolone, Propyl-metacresol, Pyridine, Resorcinol, and Saccharine, &c.

HANDWÖRTERBUCH DER PHARMACIE. Praktisches Handbuch für Apotheker, Ärzte, Medicinalbeamte und Drogisten. HERAUSGEGEBEN VON A. BRESTOWSKI. Zwei Bände. Wien und Leipzig, Wilhelm Braumüller, K.U.K. Hof- und Universitäts-Buchhändler. 1892. Erscheint in circa 24 Lieferungen zu je 5 Bogen, Lex. 8. London: H. Grevel and Co., 33, King Street, Covent Garden.

THIS new Dictionary of Pharmacy, brought out under the best auspices, is being issued in parts of large 8vo. size, bound in paper covers. The price of each part is 2.40 M., or about 2s. 5d. It contains 80 pages of Subject-matter, commencing with *Aachen* and ending with *Amylalkohol*, and counts amongst contributors the names of such men as Arnold, von Buchka, Elsner, B. Fischer, Hellmann, Jolles, Virchow, and Waage. The methods of preparation of the various drugs and chemicals described are given with great clearness and precision, space being at the same time economised to the utmost.

The contributors whose names appear along with the Editor's on the cover of each part, are 41 in number, and consist of the best known pharmacists and pharmaceutical chemists in Germany and Austria.

CHEMICAL CALCULATIONS, with Explanatory Notes, Problems, and Answers. Specially adapted for use in Colleges and Science Schools. By R. LLOYD WHITELEY, F.I.C., Lecturer on Dyeing and Assistant Lecturer and Demonstrator in Chemistry in the University College, Nottingham. London: Longmans, Green and Co. New York: 15 East 16th Street. 1892.

PROFESSOR CLOWES writes a preface to this little work, in which he points out that laboratory students will find a most useful and convenient explanation of the methods of calculating the results of specific gravity determinations, analyses, and of atomic and molecular weight determinations. We are further told, and wisely so, that it is not written for candidates for any special examinations, but for the general equipment of students of chemical science. The little work is not confined to mere problems for calculation with answers appended, but each division of the subject is prefaced by definitions, explanations, and fundamental data, so that based on these and in view thereof the student can then attempt the solution of the problems.

The subject is divided as follows:—Atomic Weights. Miscellaneous Data. Metric System. Conversion of Thermometric Scales. Density and Specific Gravity. Calculation of the Percentage Composition of a Compound. Calculation of Empirical Formulae from percentage composition. Influence of Temperature and Pressure upon the Volume of Gases. Calculations depending upon Chemical Equations. Combination of Gases by Volume. Calculation of the Results of Quantitative Analysis. Atomic Weights Determinations. Simple Calculations in Gas Analysis. Absorption of Gases by Liquids. Determination of the Molecular Weights of Compounds. Calorific Power and Calorific Intensity. Answers and Appendix. The Alphabetical Index closes the little work, which comprises 160 pages of Subject-matter illustrated by nine woodcuts representing apparatus. Price 2s.

THE TANNINS. A Monograph on the History, Preparation, Properties, Methods of Estimation, and Uses of the Vegetable Astringents, with an Index to the Literature of the Subject. By HENRY TRIMBLE, Ph. M., Professor of Analytical Chemistry in the Philadelphia College of Pharmacy. Volume I. Philadelphia: J. B. Lippincott Company. 1892. London: H. Grevel & Co., 33, King Street, Covent Garden.

OCTAVO volume, bound in green cloth and containing Preface, Table of Contents, and Subject-matter, divided into two parts. Part I. General, and Part II. Gallotannic Acid. In the Preface the author states that the title of his monograph "might well have been *A Century of Tannin*, as just about one hundred years have elapsed since tannin first became recognised as a distinct substance, or class of substances, as we now express it." The text covers 165 pages, and is sub-divided as follows:—PART I. GENERAL DESCRIPTION OF THE TANNINS. Section I. The Discovery of the Tannins. II. General Character. III. The Detection and Estimation of the Tannins. PART II. GALLO-TANNIC ACID. Section I. Sources. II. History. III. The Preparation and Purification of Tannic Acid. IV. The Properties of Tannic Acid. V. The Composition and Constitution of Tannic Acid. Then follow an Index to the Literature of the Tannins, Index of Authors, Index of Titles with Authors and Sources, and List of Books containing notable chapters on the Tannins. In the former Index the Journal of this Society figures prominently from the year 1885, in connexion with the names of Bertram Hunt, R. L. Whiteley, and especially Henry R. Procter. Two or three well-executed woodcuts representing apparatus for the analytical determination of tannin adorn the text.

ANILINSCHWARZ. Und Seine Anwendung in Färberei und Zeugdruck. von Dr. E. NOELTING und Dr. A. LEHNE. Mit 11 Abbildungen im Text und 32 Zeugdruckmustern und Ausfärbungen auf 4 Tafeln. 1892. Berlin: Verlag von Julius Springer, Monbijouplatz 3. London: H. Grevel & Co., 33, King Street, Covent Garden.

LARGE 8vo. volume, appropriately bound in black cloth, and containing Preface, Table of Contents, text covering 106 pages, followed by an Alphabetical Index of Subject-matter, one of names of authors, and 4 sheets of dyed and printed specimens in illustration of matter in the text. The text is embellished with 11 well executed wood engravings, and comprises the following sub-divisions:—Historical Introduction. Theory of the Formation of Aniline

Black. The Greening of Aniline Black. Employment of Aniline Black in Printing. I. Aniline Black in Powder. II. Formation of Aniline Black on the Tissue. Employment of Aniline Black in Dyeing. Investigation of the most important Raw Materials as follow:—I. Aniline. II. Aniline Salts. III. Chlorate of Potash. IV. Chlorate of Soda. V. Potassium Bichromate. VI. The Testing and Investigation of Aniline Black Dyes.

It is shown in the Preface that this work, originally designed to demonstrate the invalidity of the Grawitz Patents, has now become, with certain additions, an important and useful treatise in itself, and hence whilst the useful in it is now as much as possible made prominent the polemical is allowed to die out. The price of the work is 8s.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

NEW SPANISH CUSTOMS TARIFF.*

Statement showing the Rates of Import Duty to be levied in Spain under the New Spanish Tariff, compared with the Rates of Duty hitherto leviable on Imports into that Country.

Note.—Up to the 30th June next, when the Anglo-Spanish Convention of 1886 expires, the Conventional rates of the Spanish Tariff will still be levied on British produce, including those of the Franco-Spanish and German-Spanish Treaties which are enumerated in Parliamentary Paper, Commercial No. 15 (1886). (C.—478).

No.	CLASSIFICATION OF ARTICLES.	Rates leviable by New Tariff of 1st February 1892.		CLASSIFICATION OF ARTICLES.	Rates leviable hitherto on Imports from United Kingdom.
		General Tariff.	Special Tariff.		
	CLASS 1.	Per 100 kilogs. Pes. cts.	Per 100 kilogs. Pes. cts.		Per 100 kilogs. Pes. cts.
	STONES, EARTHY MATTERS, MINERALS, GLASS, EARTHENWARE, AND PRODUCTIONS OF POTTERY.				
	Group 1.—Stones and Earthen Productions employed in Building, Arts, and Manufacture.				
5	Other stones and earthenware substances employed in building, arts, and manufactures; cement, lime, and gypsum.	0 40	0 30	0 06
	Group 2.—Coals.	Per 1,000 kilogs.	Per 1,000 kilogs.		Per 1,000 kilogs.
6	Coal and coke (Note 1)	3 09	2 59	1 25
	Group 3.—Bituminous Shale, Bitumen, and Bituminous Products.	Per 100 kilogs.	Per 100 kilogs.		Per 100 kilogs.
7	Pitch, tar, creosote, unrefined, mineral oils and asphalt, bitumen, and shale (Note 2).	0 60	0 40	0 41
8	Naphtha, vaseline, crude petroleum, natural petroleum oil, and other crude oils of shale (Notes 2 and 3).	25 00	25 00	21 00
9	Benzine, gasoline, petroleum, and other refined oils (Notes 2 and 3).	40 00	40 00	32 00
	Group 4.—Minerals.	Per 1,000 kilogs.	Per 1,000 kilogs.		Per 1,000 kilogs.
10	Mineral ores	0 30	0 25	0 25
	Group 5.—Glass.	Per 100 kilogs.	Per 100 kilogs.		Per 100 kilogs.
11	Common or ordinary hollow glassware (Note 4)	13 00	10 00	6 50

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

THE PRODUCTION AND CONSUMPTION OF GAS IN THE PRINCIPAL EUROPEAN CITIES.

Board of Trade Journal, March 1892, 263.

A volume has recently been issued from the Government Printing Office at Washington containing the reports received from the Consuls of the United States in different foreign countries in answer to a circular from the Department of State as to the gas industry in the various countries.

The following particulars with regard to the chief European cities are taken from the report in question:—

St. Petersburg.—The city of St. Petersburg, numbering, according to the latest estimate, 1,000,000 inhabitants, has several gas companies in active operation at the present time. The old gas company, as it is still called, was established in 1835, and manufactures gas from bituminous coal. These works comprise 242 retorts, with an average of seven retorts to each furnace, one Beale exhaustor, six gas-holders, with a total capacity of 750,000 cubic feet, and about 3,000 gasometers. The gas production is 180,000,000 cubic feet. There are 20 gas motors, ranging from 4 to 10 horse-powers. The aggregate length of the mains is 28 miles, with pipes varying from 2 to 30 inches in diameter.

The Metropolitan Gas Lighting Company of St. Petersburg supplies a large portion of the city with coal-gas, using 62,450 tons of coal per year. The price for lighting the streets for an aggregate of 3,200 hours has been 3*l.* 0*s.* 5*d.* per lamp. For Government buildings the price has been 6*s.* 1*d.*, and for private consumers 7*s.* 1*d.* per 1,000 cubic feet. Recently the company has reduced these prices to 4*s.* 8*d.* for technical purposes, 5*s.* 5*d.* for private consumption. These works contain three groups of condensers, six ordinary scrubbers, two "Standard" scrubbers, 32 purifiers, six gas-holders with a capacity of 2,000,000 cubic feet, five regulators, five gas-meters, and six steam engines. The gas production in 1887 was 637,496,200 cubic feet. There were 7,852 street lamps, 120,524 private burners, and 72 gas motors aggregating 319 horse-power. The total length of the gas mains is about 165 miles.

The gas works of Vassili Ostroff, an island on the north side of the river Neva, and forming a portion of the city of St. Petersburg, furnish a large portion of the gas for the inhabitants of the island. These works contain nine Biley's exhaustors, and manufacture gas from coal in the usual manner. The returns from these works consists of 44,469 tons of coke, 2893 tons of tar, and 5,416 tons of ammoniac water. The number of consumers is about 3,200, with an equal number of gasometers. The aggregate length of the main is about 27 miles.

The gas works of the Wiborg and old St. Petersburg portion of the city of St. Petersburg belong to a limited company and manufacture gas from Newcastle coal, the quantity of coal used being 7,717 tons per annum. The gas production in 1888 was 73,128,630 cubic feet. There were 1,457 street lamps and 10,500 private burners in the same year. The gas works of the Marshall Academy belong to the same company, and from both of these works there are obtained annually 5,152 tons of coke and 302 tons of tar.

In addition to the cities and towns enumerated above, employing gas for lighting and heating purposes, there are about 40 railway stations in the Empire lighted either with coal-gas or petroleum-gas and about 160 gas manufactories established in separate buildings for the use of factories, stores, banks, and other private enterprises of various descriptions.

The laws of Russia forbid the manufacture and use of water-gas, on the ground that the gas is injurious to health. There is a special article in the patent laws of the country to the effect that no mechanical device, nor any chemical combination producing articles injurious to the health of the people are patentable, and if patented under disguise or ignorance of this fact the patent becomes invalid. Many parties have made repeated efforts to introduce

water-gas in Russia, but all such applications have been rejected, invariably meeting with the unanimous opposition of the Imperial Society for the Preservation of Health.

Berlin.—In the city of Berlin there are two gas companies: (1.) The City Gas Company, owned and operated by the city; (2.) The Imperial Continental Gas Association, owned and operated by an English company.

The former company has four separate gasworks in the city. The latter company has three separate gasworks in Berlin and suburbs.

It appears that privileges were granted to the English company as far back as 1827. By contract made with the town of Schönberg in 1854, this company has the exclusive right to lay pipes in that quarter of Berlin, which has since been acquired from Schönberg. These privileges may to a certain extent account for the difference in price between the gas supplied by the city works and that supplied by the English company.

During the fiscal year ended March 31st, 1889, there were nearly 4,000,000 cubic metres less gas used in the city of Berlin than in the preceding year. This decrease is supposed to be due to the influence of the growth of electric lighting and especially to the successful efforts of the lamp makers in producing lamps with larger and better burners.

The number of electric lights in use in Berlin during the year ended March 31st, 1889, was 66,650.

During the calendar year 1887 the city of Berlin consumed 47,299 tons of petroleum, and in the year 1888, 54,138 tons, or an increase of 15 per cent.

The quantity of gas produced by the city gas works during the year 1889 was 90,000,200 cubic metres.

The number of jets fed by the city gas works was: Public, 17,509; private, 798,631; gas works and offices, 3,309; total, 819,449.

The quantity used by the public lights was 11,489,208 cubic metres; by the private lights, 68,608,759 cubic metres.

The city gas works used 314,264 tons of coal from the Silesian coal-fields, the product in gas for each ton of coal being 287·05 cubic metres.

The length of the net work of pipes used by the city gas works was 693,493 metres.

The value of the gas used in gas works and bureaux was estimated at 13½ pfennigs per cubic metre. The value of the gas used for other purposes than lighting was estimated at 12·8 pfennigs per cubic metre. The value of the gas used for lighting was estimated at 16 pfennigs per cubic metre.

The total income of the city gas works was as follows:—During the year 1889, from gas, 11,552,591 marks; use of gas metres, 268,323; coles, tar, &c., 4,443,357; total, 16,264,271.

The total expense of the city gas works during the same year was as follows: Cost of coal, 5,614,245 marks; firing, 701,626; purifying material, 10,596; wages, 588,918; interest on plant, 884,270·11; other expenses, taxes, insurance, &c., 3,414,789; total, 11,214,444.

These figures show an excess of receipts over expenses of 5,049,826·45 marks.

There are no official statistical data at hand respecting the income and expenses of the English company which supplies one-third of the gas consumed in the city of Berlin.

Paris.—The gas company known under the name of *Compagnie Parisienne d'éclairage et de chauffage par le gaz*, which has the sole permission to furnish the city of Paris with gas, was founded in the year 1855. The capital subscribed amounted to 3,377,500*l.*, divided into 336,000 shares at 10*l.* 1*s.* each. These are worth now about 52*l.* 1*s.* 8*d.*

The total receipts for the year 1889 amounted to 4,247,780*l.*, of which 3,243,410*l.* were for gas, 677,924*l.* for coke, and 142,112*l.* for other by-products. The expense, amounting to 2,645,909*l.*, comprised 847,379*l.* for coal, 175,483*l.* for labour, 63,356*l.* for engineers and salaried working staff, 42,535*l.* for the central administration, 12,062*l.* for the direction, 361,201*l.* for redemption of capital, 273,046*l.* for municipal charge, including the tax of 1*d.* per cubic metre.

The net profits for the year amounted to 1,588,229*l.*, of which 1,019,281*l.* go to the stockholders, and 360,614*l.* to the city of Paris. The dividend for the year was 3*l.* 2*s.* 6*d.*

The gas is manufactured from coal by the ordinary process and is assayed every day before delivery as regards its lighting power and purification by company agents, and also by agents appointed by the city authorities.

According to contract the gas delivered for consumption by the Parisian gas company must be perfectly purified and its lighting power under a pressure from 2 to 3 millimetres of water, and an average consumption of 105 litres of gas per hour, be equal to the light of a lamp burning 42 grammes of pure colza oil per hour.

The report of the Paris Gas Company for 1889 showed that the consumption in the year amounted to 312,000,000 cubic metres (11,013,000,000 English cubic feet).

The annual consumption of gas in Paris has gone up from 218,813,875 cubic metres in 1879 to 297,258,070 cubic metres in 1888.

The annual consumption of gas rose during the same period for the whole of France from 467,500,000 cubic metres in 1879 to 628,000,000 cubic metres in 1888.

The number of subscribers to the Paris Gas Company for 1889 was 224,119, an increase of 11,604 over the year 1888.

The substitution of electric lighting in a number of theatres, public establishments, and thoroughfares has been compensated by the increased use of gas for domestic purposes, and the day consumption now exceeds 26 per cent. of the total, and equals one-third of that in the dark hours.

The Paris Gas Company delivers the gas used for public lighting at the rate of 3*s.* 5*d.* per 1,000 cubic feet, and for private use at the rate of 6*s.* 8*d.* per 1,000 cubic feet.

The apparatus which permit the use of gas in kitchens (cooking stoves, ovens, griddles, &c.), in dressing rooms, kettles and bath heaters in private apartments (stoves), are becoming more and more frequently used.

The fact that in Paris one-fifth of the gas supplied by the gas works is consumed during the day indicates the importance of consumption other than for lighting purposes.

The men in charge of the furnaces are paid 2*s.* 8*d.* per 1,000 kilos. coal; they are on duty 12 hours each day, and their daily earnings are from 9*s.* 7*d.* to 12*s.* 1*d.* Coal carriers and cartmen are paid from 3*s.* 4*d.* to 4*s.* 2*d.* for a day's work of 10 to 12 hours.

The coal used in the manufacture of gas by the Paris company is obtained in France, Belgium, England, and Germany at an average price of 12*s.* 1*d.* to 1*l.* 7*d.* per ton.

Brussels.—Brussels has its own gasworks, maintained by the municipality. The suburbs are supplied by the Company General and Imperial Continental Gas Company.

Gas is obtained by the decomposition of coal by heat. The coal is heated in angular cylinders, holding about 200 lb. of broken coal. The gas is passed from the cylinders into coolers, is then purified and ready for use. Two hundred pounds of coal yield on an average about 25 cubic metres of gas, 8 lb. of coal tar, and 2½ bushels of coke. About one-third of the coke thus obtained is employed in heating the cylinders, the remainder is sold for domestic use.

The candle power is 7½ candles, or 105 quarts of gas per hour. Approximate annual output of the city of Brussels, 14,226,787 francs. Number of consumers, 19,152.

The price of gas differs more or less according to locality, varying 10 to 25 centimes per cubic metre, as follows:—

In the city of Brussels, day consumption, 10 centimes per cubic metre; night consumption, 15 centimes per cubic metre. The suburban consumers of Etterbeck, Forest, St. Gilles, Ixelles, Kocheberg, Molenbeck, and Peele, 15 centimes per cubic metre. St. Jean-Ten-Noode, 18 centimes; Schaerbeek, 20 centimes; and Laeken, 25 centimes per cubic metre.

Wages paid to workmen employed in the Brussels gasworks vary from 3 to 5 francs per day for 11 hours' work. In the provinces of Brabant, Haicant, and Namur, 11 and 12 hours' labour is exacted for wages varying from 2 to 4.50 francs per day.

Rome.—The Anglo-Romano Company for the lighting of Rome have the monopoly of supplying the city both with gas and electricity for purposes of illumination.

They have two gasworks, one on the Via dei Cherehi, and one on the Via Flaminia. The process described is that employed at the larger works on the Via dei Cherehi, but it is substantially the same at each.

The coal used is from Newcastle, mixed with 5 per cent. of Liverpool canal coal, and costs from 1*l.* 5*s.* 9*d.* to 1*l.* 6*s.* 7*d.* delivered at the works. At this price the company has a contract which has some time to run, although the market price has advanced to about 2*l.* 0*s.* 3*d.* per ton.

The retorts used are of clay, and measure 21½ in. wide, 11 in. high, and 9 ft. 6 in. long. They are made in Italy, are much better than the French manufacture, and are equal to the English, but cost less. They are placed in groups of seven and eight around the furnaces. There are 78 furnaces that heat 562 retorts. Each retort has a capacity of 160 kilos. (353 lb.) and is charged and drawn by hand.

All the furnaces are duplex, the invention of Mr. Walter R. Jones, the engineer of the works, who has secured patents on them in Europe and the United States. This pattern of furnace has been in use since 1884, and has given excellent results, all the regenerative furnaces having been transformed in preference.

The number of public gas lights in Rome in 1888 was 6,033, the public consumption of gas was 115,650,000, and private consumption 381,550,000 cubic feet. The cost per 1,000 cubic feet for public consumption was 5*s.* 7*d.*, for private 6*s.* 7*d.*

Twelve hours constitutes a day's labour, and the wages paid are about as follows:—Head mechanics per day, 4*s.*; mechanics and machinists, 2*s.* 10*d.*; superintendent of firemen, 4*s.*; firemen's corporal, 3*s.* 7*d.*; firemen, 3*s.* 2*d.*

For good conduct a bounty is given to the firemen's corporal of 8*s.* 1*d.* A pension of 4*s.* 2*d.* per week is paid to the widows of workmen so long as they remain widows.

Constantinople.—Gas has been in use in the city of Constantinople for the last 30 years, but was limited to one part of the city, namely, Pera, and is the residence of all Europeans and foreigners in general, as well as of all the ambassadors, ministers, consuls, &c.

There are two gas companies in Constantinople. The first is a Turkish company, under the general management of and belonging to the Imperial Turkish Government, and is called Imperial Gas Works. The factory of this company is situated in Dolma Baghtché, a suburb on the Bosphorus, and furnishes gas for the use only of Pera, the Imperial palaces on the Bosphorus, the lower end of Pera, which is called Galata, and of one or two villages on the Bosphorus.

The second company is a Belgian-German concern, which obtained the necessary concession from the Turkish Government about two years ago, and is called *Société Ottomane pour l'Eclairage de la ville de Constantinople*. This company has established a factory at the Seven Towers, on the Sea of Marmora, and has the privilege of supplying gas only to the other side of the city of Constantinople, properly called Stamboul, which is largely inhabited by the Turks, including the suburb of Eyoub in the Golden Horn.

It is impossible to ascertain the amount of money invested in the industry by the first Government company. The amount invested by the second, the Belgian-German, is 152,078*l.*

Process of manufacture: The factory of the Belgian-German company was constructed by Mr. Kloenne de Dortmund. It has a gasometer of 12,000 cubic metres, with furnaces and four batteries, with eight retorts each. The other machinery is in proportion.

The machinery hall is 90 metres long by 15 metres wide; the furnace hall is also 90 metres long by 15 metres wide.

Brilliance of gas, 12 to 14 candles.

The approximate annual output is 1,000,000 cubic feet in Stamboul, and 3,000,000 cubic feet in Pera and Galata.

Number of consumers: The Belgian-German company has about 10,000 to 12,000 flames for the present. No statistics can be obtained from the Government company.

The price of gas per 1,000 cubic feet is 7s. 4d., with 25 per cent. discount for public fixtures.

The use of gas stoves for heating and cooking is quite limited.

The wages of the employes of the Belgian-German company range as follows: Director, 1,000*l.* per annum; chief engineer, 680*l.*; quartermaster, 165*l.*; other employes, 40*l.* The hours of labour are about 12, with rests two or three times during the day or night.

The material used is English Newcastle and Cardiff coal. The price is 1*l.* 6s. 3d. to 1*l.* 7s. 3d. per ton.

Christiania.—Christiania, the capital of Norway, situated at the inner end of the Christiania Fiord, has a population of 145,000.

The Christiania gas works belong to the community. The amount invested by the city is reported to be 91,960*l.*

The gas produced is the ordinary coal-gas. The process done by sulphurous acid and ferric oxide.

The power of gas is equal to 16 candles.

The annual output is 167,000,000 cubic feet. Number of consumers, 3,205.

Price of gas for illumination, 4s. 9d. per 1,000 cubic feet with 5 or 10 per cent. discount for consumers, in proportion to quantities used. Price of gas for cooking and technical purposes, 3s. 2d. per 1,000 cubic feet without discount.

Number of gas stoves for heating, 20; cooking, 300; gas motors, 13.

Wages of employes, from 2s. 3d. to 3s. 4d. for 12 hours of labour per diem.

New Pelton coal from Newcastle. Their cost in 1889, 1*l.* 1s. English per ton.

Copenhagen.—In the year 1886 Danish gas works manufactured 989,631,720 cubic feet of gas. Out of this amount Copenhagen produced 594,517,300 cubic feet, or about 60 per cent. of the whole kingdom's gas, and $1\frac{1}{2}$ times more than all the other gas works in Denmark together. If the suburb of Frederiksberg be counted as part of the capital, Copenhagen consumes more than twice as much gas as the rest of the country.

Of gas manufactured in Denmark, 83·8 per cent. is produced by municipal gas works, and only 16·2 per cent. from private works. A steady increase has taken place during the last years. In 1881 the production was 705,731,600 cubic feet, and the increase has therefore been 38·9 per cent. The increase in the gas production at the Copenhagen gas works was during the same period 1881—86, 27 per cent., or about $4\frac{1}{2}$ per cent. a year. The other municipal gas works had at the same time an increase of 63 per cent., while private works had about 60 per cent., equal to a yearly increase of about 10 to 12 per cent.

Berne.—The money invested in the gas works at Berne amounts to 1,728,569 francs.

Process of manufacture: gas is manufactured exclusively in retort stoves. The manufacture of carbonated gas is not known in Switzerland.

It is prescribed here that a gaslight consuming 150 litres per hour must have at least a power of 16 Amplaectats lamps.

Approximate annual output: in 1889, 1,872,470 cubic metres gas were produced at Berne.

At the end of 1889 Berne had 1,741 gas metres for lighting purposes, 22 for machines, and 244 for gas stoves; total consumers, 2,027.

Price of gas for illuminating purposes, 25 centimes per cubic metre.

The use of gas stoves is annually increasing. The price of gas for this purpose and machines is 20 centimes per cubic metre.

Wages: stokers receive from 3·60 to 4 frs. for nine hours' work; still their presence is required for 12 hours, of which time they have three hours idle.

For the manufacture of gas, Saar (Germany) and St. Etienne (France) coals are now used, with boghead of Autun (France), Tyne boghead (England), and pitch coal from Bohemia to gain the prescribed light power.

Price of coal at the gas works, Berne: Saar, per 100 kilogrammes, 3·24 frs.; St. Etienne, 3·22 frs.; French boghead,

7·30 frs.; Tyne boghead, 6·50 frs.; Bohemian pitch coal, 4·70 frs.

Greece.—Cities using gas: Athens, Piræus, Patras, and Corfu.

Names of companies: Athens, *Compagnie d'Éclairage pour le Gaz pour la France et l'Étranger, Siège social, Paris*. Piræus, *Société Belge*. Patras, the municipality is owner of the gas works. Corfu, English company.

Amount of money invested in the industry: Athens, 2,000,000 frs.; Piræus, 1,050,000 frs.; Patras, 800,000 frs.

The process of manufacture is by distillation of coal.

The candle power of gas is 5·16 and 10 candles, counted in carrels.

The approximate annual output cannot be given.

Number of consumers: Athens, 1,400; Piræus, 350; Patras, 300.

Price of gas per 1,000 cubic feet: Athens, 37 lepta the cubic metre; Piræus, 35; Patras, 27.

Some gas stoves used for cooking, none for heating.

Wages, 3 frs. to 3·50 frs. per day. Hours of labour, 9 to 10.

The material used in the manufacture of gas is coal—Cardiff and Newcastle; about 35 drachmas delivered in the harbours of Piræus, Corfu, or Patras.

BURNT CLAY MORTAR.

United States Consular Reports, October 1891, 181.

In the frequent eruptions of Mount Etna in times past great beds of clay have been covered by lava which has burnt and converted them into a fine red gravel or powder. This burnt clay, when mixed with a little lime and water, forms a mortar locally considered superior to any other cement for building purposes. Every building in Catania is constructed of lava liberally cemented with this mortar, giving a peculiar soft pink colour to all the unpainted buildings. In building, small irregular stones are used just as they happen to come, and a smooth surface is afterwards given by a thin coating of mortar inside and out, which can then be divided by a trowel to imitate blocks of stone. The harbour breakwater (which extends for three-quarters of a mile into the sea) was constructed in this way ten years ago, and is as good to day as when first built.

—G. H. B.

WHITE WAX IN CHINA.

United States Consular Reports, October 1891, 201.

In Western China, not far from the Tibetan frontier, flourishes the tree *Ligustrum lucidum*, called by the Chinese "evergreen tree," bearing thick dark green glossy leaves with clusters of small white flowers in the summer, which are succeeded by fruit of a dark purple colour. Early in the spring numerous brown pea shaped scales appear on the boughs and twigs of the tree containing the larvae of the wax insect whose scientific name is *Coccus pe-la*. These scales are gathered by the Chinese, wrapped in packages, and conveyed about 200 miles to Chia-ting, the centre of the industry. The scales are here made up into small packets with leaves and are suspended under the branches of a species of ash. The insects on emerging from the packets creep up to the leaves of the tree and afterwards descend to the twigs and branches where the wax is deposited by the male insects. After 100 days the deposit is complete and the branches are then cut down, the wax scraped off, and what remains on the twigs is separated by boiling with water, which destroys the insects and necessitates a fresh supply of larvae in the next year from outside districts. A pound of larvæ scales will produce 4 or 5 lb. of wax, a ton of which is worth about 1,000 dollars at Shanghai. A tree from which the branches are removed is only available again after three years. The product is a clear white wax melting at 160° F., and is chiefly used to cover candles made of animal and vegetable tallow. It is also used for sizing paper and cotton goods, as a glaze for silk, and a polish for furniture. The introduction of foreign kerosene has had a discouraging influence on the production of white wax by diminishing the demand for candles.

—G. H. B.

THE PITCH LAKE OF TRINIDAD.

United States Consular Reports, October 1891. 254.

The sum of 26,744*l.* was derived in revenue from the pitch lake in 1890. The extension of the concession of the pitch lake was approved for an additional year for every 4,000*l.* which shall be paid by the concessionnaires before February 1st, 1909, over and above the minimum sum of 140,000*l.* payable in respect of the first term of 14 years, and the further sum of 28,600*l.* payable in order to obtain the extension of seven years from February 1st, 1902. One of the conditions imposed was that on February 1st, 1891, the concessionnaires should make a special payment to the colony of 10,000*l.*, in addition to the regular payment of 10,000*l.* due on that day under the terms of the concession, both payments being taken as against shipments of the year commencing on that day. Further, the Trinidad Asphalt Company agreed that if by February 1st, 1892, the concessionnaires had not paid to the Colonial Government 100,000*l.* in addition to the permanent deposit in London of 10,000*l.* the company should on that day give to the Crown free on all the land it now possesses in Trinidad a general security for the balance then remaining of the 140,000*l.*, the payment of which to the Colonial Government the company has undertaken.—G. H. B.

SULPHUR MINING IN SICILY.

United States Consular Reports, November 1891. 363.

The mining and fusing of sulphur in Sicily is still carried on in a primitive fashion owing to want of capital. Machinery is very little used and hand labour is universal. The two processes mostly used for obtaining sulphur are carried on in furnaces heated by the sulphur rock, and the acid fumes given off are very destructive to vegetation. A process recently imported from Spain gives a much improved yield, a sulphur ore containing 15 per cent. of sulphur giving a yield of 12.2 per cent. of sulphur, while the ordinary process yields only 5.6 per cent. of sulphur from the same material. The richness of the mineral in the mines is subject to great fluctuation, the risk of which becomes an objection to the erection of expensive plant. The Sinopoli furnace, which is much in use, consists of a number of iron cases about two metres long, three metres high, and a quarter metre wide; they are surrounded by walls and heated by two furnaces. When the requisite temperature is attained the sulphur melts and runs off through holes in the lower part of the cases, the operation lasting about 30 hours. Nine dollars per ton is given as a low estimate for the cost of mining and fusing of the sulphur. The prices of the various grades of sulphur differ by only small increments as shown in the following list of prices per 100 kilos. :—

Description.	Price.
	Lire.
First grade (best).....	10.71
Second grade :—	
Best	10.57
Good	10.44
Current	10.12
Third grade :—	
Best	9.85
Good	9.77
Current	8.70

—G. H. B.

THE CHEMICAL INDUSTRY OF BERLIN.

United States Consular Reports, November 1891. 403.

In the year 1890, taken as a whole, the chemical industry of Berlin was in a very satisfactory condition in spite of

constantly increasing cost of production, due to increased prices of coal, raw materials, and labour, and to the burdens imposed by State legislative measures adopted for the good of the working classes, but on account of increasing competition, sale prices did not improve. The production did not decrease in quantity, but, on the contrary, in some articles increased very considerably. The price of sulphate of ammonia averaged 26 marks, ammonium carbonate 65, while crystallised sal-ammoniac 58 to 60, and liquor ammoniac (sp. gr. 0.91) 33 marks per 100 kilos. Quotations for potassium carbonate of 96 to 98 per cent. were 36 to 37 marks per 100 kilos. The trade in oxalic acid was very active at cheap prices, averaging 55 marks. In potassium chlorate there was decided over-production, and the price fluctuated between 90 to 100 marks. The increased cost of alkali used for sodium silicate did not lead to increased price of the product as there was an over-production, although the demand increased. Soda ash and caustic soda rose steadily in price, but soda crystals were over-produced and prices did not continue to rise. Sulphuric acid of 66° was equal to the demand at 7 marks per 100 kilos. Prices for Chili saltpetre rose near the end of the year. The quotation for nitric acid of 36° was 23 marks. The condition of the tar industry was uninterruptedly satisfactory. Benzol rose 25 per cent. in price and the manufacture of naphthalene was especially lucrative. Toluene also found increased demand. Anthracene found steady sales at unchanged prices. The value of crystallised carbolic acid, previously in large demand at enhanced prices for military purposes, fell from 11½*d.* to 5½*d.*, but a rise is now to be expected. Prices of coal-tar colours were unchanged and any hopes of renewed success in this branch lies in patented specialities. The demand for aniline oil and aniline salt was unusually strong and prices rose considerably. The prices of chemical mineral colours advanced 15 per cent. over those of 1889. In Berlin and its vicinity, where wages are high and the entire cost of manufacture dear, only first class wares can be manufactured, whilst the cheap products (earth colours, &c.) are made in provincial factories.

On the whole the Berlin chemical mineral colour industry fully maintained its position in the trade of the world, except in a few countries from which it is kept out by Customs duties. Chemicals for pharmaceutical, photographic, and technical purposes were in active demand, but profits arising from their manufacture were not increased.

The requirements in regard to chemical purity of various pharmaceutical preparations have considerably increased since the publication of the third edition of the German Pharmacopœia, but the increased expense necessitated in obtaining the desired qualities finds little expression in increased prices. The price of bromine remained unchanged, but the prices of bromine preparations fell on account of continued competition among manufacturers. The consumption of chloral hydrate decreased on account of the increased use of other hypnotics, and the price fell 50 per cent. The selling price of potassium cyanide was not affected by the rise in price of its raw material, yellow prussiate of potash. The glycerin market, on the whole, was stagnant in 1890, and quotations for refined or distilled wares, owing to sharp competition, at no time during the year showed the proper relation to the value of raw material.—G. H. B.

GENERAL TRADE NOTES.

PALM OIL.

J. Soc. Arts, 40, March 18, 1892, 407—408.

The total import of palm oil into England is about 50,000 tons, valued at over 1,000,000*l.*, but it is considered that this is an exceedingly small commerce compared to what might be the case were the enormous resources fully, or even moderately, utilised. For miles along the west coast of Africa, extending between Cape Bianco and St. Paul di Loando, there are vast forests of palms, the oleaginous fruit of which has, for centuries, rotted unused upon the ground. The oil-palm

forests at the back of the coast-line of Cape Palmas and Elmina are said to be practically inexhaustible; and so also in the neighbourhood of Fernando Po, immense tracts are covered with the trees.

Lagos furnishes the purest oil; for there are in commerce regular and irregular oils. When analysed, if the water and impurities exceed 2 per cent., an allowance is made; for often these oils contain 10 to 15 per cent. of water and impurities.

Palm oil is eaten as butter by the natives, and used for anointing their bodies. Here it is used in the manufacture of soap and candles, and in South Wales in the preparation of tin plates. Its non-drying qualities render it valuable as a preservative of the surface of the heated iron sheet from oxidation until the moment of dipping into the bath of melted tin, the sheets being rapidly transferred to that from the hot oil-bath, which consists almost entirely of palm oil.

In 1871, as well as in 1880 and 1891, the imports of palm oil into the United Kingdom exceeded 1,000,000 cwt. From 10,000 to 15,000 tons of palm oil are shipped direct from Africa to the Continent. The price of the oil has ranged from 35s. per cwt. in 1883 to 23s. in 1890.

INCREASED CONSUMPTION OF BORIC ACID IN FRANCE.

In 1881, 2 kilos. of boric acid sufficed for the whole of the Paris hospitals, but, thanks to the progress of antiseptic surgery, though consumption began to increase in the year following, by 1884 the quantity rose to 1,057 kilos., and in 1890 there was required 8,085 kilos. of the acid. There has never been the slightest fluctuation, simply a steady increase. —*Chemist and Druggist*.

SYNTHESISING TARTARIC ACID.

M. Genvesse has discovered a simple way of synthesising tartaric acid. He starts with glyoxalic acid ($\text{CHO} \cdot \text{CO}_2\text{H}$), the acid peculiar to gooseberries, grapes, and similar fruits; and, by acting upon it with nascent hydrogen liberated by the action of acetic acid upon zinc-dust in contact with the glyoxalic acid, two molecules of glyoxalic acid are joined together by two hydrogen atoms, and that union gives tartaric acid, or rather the optically inactive form of it known as racemic acid, there being apparently equal molecules of the dextro- and levo-varieties produced. The product was separated and examined. This new synthesis of tartaric acid would appear to throw some light upon the natural formation of tartaric acid; for, remembering the close relationship between glyoxalic and oxalic acids, which latter is one of the most readily formed in vegetable tissues, and the reducing agencies which appear to be connected with chlorophyll, we have all the means at hand to account for the natural synthesis of tartaric acid. —*Ibid*.

THE ALKALI INDUSTRY.

The United Alkali Company (Limited) have closed their works at Clyde Bank, and are greatly restricting the production at their Irvine and Eglinton establishments. They have arranged with another firm to control the production of bleaching-powder. Chemical works are to be established close to the salt works, situated some miles beyond Fleetwood, and the erection of buildings is expected to be commenced immediately. Employment will be afforded to 1,000 workmen. The North chemical works at St. George's, Bristol, have been reconstructed so as to increase their powers of production. The North British chemical works at Glasgow are being dismantled, and most of the plant, which is said to be the best of its kind in the country, is to be removed to one of the other works of the Alkali Union, with which the concern has been incorporated. —*Ibid*.

THE PORTLAND CEMENT INDUSTRY.

Bradstreet's for the 13th February publishes the following abstract of a paper by M. Pierre Giron, recently read before the Engineers' Club at Philadelphia:—

"The present annual production of Portland cement in Europe amounts to over 20,000,000 barrels, and its commercial value to over 36,000,000 dols. The first factory was established at Northfleet, on the Thames. The process was so crude that in 1850 only four factories were in operation.

In England there are now over 8,300,000 barrels made each year. The process used there is about the same as it was 20 years ago. The raw materials are chalk and clay, both very pure, and, although inferior processes are used, they make a satisfactory cement. A few years ago the entire product of the kilns was put on the market, but the fineness of the continental cements led English makers to improve their qualities, although even now English cement is not, as a rule, as firm as Geneva or French Portland.

"The manufacture was first introduced into Germany in 1852. To-day there are 60 large works, having the same annual production as England. The raw materials are of exceedingly unfavourable character, but the makers have made a serious study of the properties and uses of Portland cement, and the producer now knows exactly what rules to follow to regulate his operations, and the consumer can depend on the product offered him. The Association of Manufacturers has had much to do with the immense development of the industry in Germany.

"In France the industry grew slowly, the total output in 1880 hardly exceeding 750,000 barrels a year. To-day the output is 1,800,000 barrels. The works of the Company of French Cements at Boulogne-sur-Mer form the largest Portland cement factory in the world, turning out about 800,000 barrels a year. In Russia the first works were established in 1857, and there are now eight Portland cement works, making 900,000 barrels a year. In Belgium there are four works, producing 800,000 barrels. In Italy the Portland cement industry does not properly exist, although a certain kind of natural Portland is made. In Denmark, Norway, and Sweden there are 10 factories, making about 800,000 barrels.

"Portland cement was imported into the United States as early as 1868. In 1882 the amount imported was 370,406 barrels, and last year it exceeded 3,000,000 barrels. But little effort has been made to develop the manufacture there. The materials for manufacture are as hard to handle as any in Germany, and the processes are similar. These are:—1, Grinding the rock into fine powder; 2, moulding it into bricks; 3, drying the bricks; 4, burning in an intermittent kiln with alternate layers of coke; 5, grinding the clinkers.

"These operations require about eight days, and require great care to produce a uniform product. The cost of the system is too great to make it successful in America. The process used in the Portland cement works at Coplay, Pa., has entirely revolutionised the science of cement-making. Here the raw compound is burnt in a powdered condition while travelling in an inclined rotary furnace in an intensely hot petroleum flame, and a few hours is sufficient to finish the process. The cement is guaranteed to stand 400 lb. in seven days, 500 lb. in a month, and 600 lb. in three months, and to leave no more than 10 per cent. residue on a No. 80 sieve."

GERMAN CHEMICALS IN INDIA.

The development of the German steam service with the East reveals the growing power of Germans in the Indian market in a manner that would have been impossible if nearly all goods were still shipped by way of this country, as in former days. The official Indian statistics recently published give the following particulars of some of the imports into British India from Germany:—

	1889-90.	1890-91.
	Rupces.	Rupces.
Chemicals (undennominated)	18,507	43,311
Quinine	6,312	24,256
Medicines	48,430	70,964
Opium	10	100
Aniline dyes	208,355	297,014
Other dyes	1,020	2,902
Instruments and apparatus	40,471	100,470

The total value of all goods imported into India from Germany has been:—In 1886–87, Rs. 1,603,000; 1887–88, Rs. 1,944,920; 1888–89, Rs. 2,480,160; 1889–90, Rs. 5,639,120; 1890–91, Rs. 16,916,490.—*Chemist and Druggist*.

THE PRODUCTION OF PHOSPHORUS.

Until a few years ago the countries of Central and Northern Europe obtained nearly the whole of their phosphorus from England, while France sent part of her surplus production to Spain and Italy. But gradually Russia has secured a not inconsiderable share of the Central European trade, a fact plainly shown in the German statistics concerning the importation of phosphorus, which are as follows:—

Imports from	1885.	1887.	1889.	1890.
	Tons.	Tons.	Tons.	Tons.
England	177	176	212	67
France	2	9
Russia	17	38	21
Other countries	2	2	..	25
Total	179	195	252	120

—*Ibid.*

COMMERCIAL MUSEUM AT CONSTANTINOPLE.

An intimation has been received from Messrs. Richard Shaw and Co., of Liverpool, to the effect that a permanent exhibition for displaying samples of produce and manufactures has been established at Constantinople.

Its object is to draw attention to and make known throughout the Ottoman Empire, as well as in foreign countries, the different kinds of hand and machine-made goods, and to give a larger extension to the demand for these goods by having permanently on show, in premises specially adapted for the purpose, properly classified samples, and by this means to contribute towards the extension of the commercial relations of the country with other States. The exhibition will be divided into two sections.

The first will contain samples of raw material produced in the Empire, specimens of manufactures, and other articles of Turkish make; while in the second section will be classed samples of British and foreign manufactures and products of all kinds. The museum will include a special bureau of commercial and industrial information, which will supply all possible details as to Customs tariffs, cost of goods at the place of production and their selling prices at the markets of consumption, the cheapest means of conveyance by sea and land, the charges attending the import and export trade with Turkey, and how such may be reduced to their lowest possible limits, with every other information on commercial matters that may be required.

The directors of the museum have the option of acting as intermediaries on behalf of manufacturers or merchants, who, with a view to protect their wares against spurious imitations, may be desirous of benefiting by the provisions of the law relating to trade marks, &c., or on behalf of inventors desirous of obtaining patents. A special book will be kept at the store in which entries will be made of the nature, quantity, value, place of origin, and the names of the senders of all goods exhibited in the magazin and sold through the medium of the directors, as also particulars of any improvements effected in the different articles of industrial produce.

The following are the rates for space in the museum:—1*l.* 7*s.* 3*d.* per square metre per annum; 18*s.* 2*d.* per $\frac{2}{3}$ of a square metre per annum; 13*s.* 8*d.* per $\frac{1}{3}$ of a square metre per annum; 9*s.* 1*d.* per $\frac{1}{4}$ of a square metre per annum, for samples of any article or product whatsoever.—*Board of Trade Journal*.

PETROLEUM PRODUCTION IN THE UNITED STATES IN 1891.

Bradstreet's of the 30th January says that:—

"The petroleum production in the United States in 1891 was the largest in the history of the industry. In 1889 the total production was 35,163,513 barrels, of which Pennsylvania and New York produced 21,487,135 barrels; Ohio, 12,471,466 barrels; West Virginia, 544,113 barrels; Colorado, 316,476 barrels; California, 303,220 barrels. The remainder was produced in Indiana, Kentucky, Kansas, Texas, and Missouri. No detailed figures have been published for 1890, but production was in the neighbourhood of 46,000,000 barrels, of which about 29,000,000 were produced in New York, Pennsylvania, and Northern West Virginia, a little over 1,000,000 in the Macksburg district, over 15,000,000 in Lima, and 1,000,000 in other districts, making a total of 46,000,000. The production in 1891 was approximately 50,150,000 barrels, of which Pennsylvania, New York, and West Virginia produced about 34,500,000 barrels; Macksburg, less than 100,000 barrels; Lima, about 14,500,000 barrels; California, 350,000 barrels; Colorado, 325,000 barrels; and the rest of the country 50,000 barrels."—*Ibid.*

THE ADULTERATION OF FERTILISERS.

The Departmental Committee which Mr. Chaplin has appointed to inquire into the question of Agricultural Fertilisers consists of the following members:—Mr. J. S. Gathorne-Hardy, M.P., Sir Jacob Wilson, Dr. James Bell, C.B., F.R.S., Mr. J. F. Rotton, Q.C., Mr. Channing, M.P., Mr. P. McLagan, M.P., and Mr. Albert Pell, with Mr. R. T. Crauford as secretary. The following are the terms of reference:—"To inquire into and report upon the representations made by Chambers of Agriculture and other bodies or persons with reference to the adulteration of artificial manures and fertilisers and feeding stuffs used in agriculture, and to receive and report upon any evidence which may be forthcoming on the subject, and to consider whether special legislative provisions for the prevention and detection of the adulteration of the commodities referred to appear to be necessary, and if so, the nature of those provisions."—*Standard*.

NEW PATENT LAW OF GERMANY.

In a recent report to his Government, the United States Consul-General at Berlin encloses the following translation of an extract from the *Hanover Courier* concerning the provisions of the new patent law of Germany:—

The new patent law, which went into force on October 1st, contains a number of provisions which differ very materially from the former requirements of law, and a knowledge of these new provisions is therefore of great importance both to producers and consumers of patented articles. While formerly the industrial use of products manufactured according to a patented process was not under patent protection, a paragraph added to section 4 of the new law provides that the effect of the granting of a patent for a process extends also to articles produced directly by such process. Accordingly, a dyer who obtains and uses in Germany dyestuffs which are patented in Germany, but which are produced in Switzerland without the consent of the owner of the patent, makes himself liable for breach of patent. This point was doubtful under the old law. The prosecution for such breach of patent is rendered easier for the owner of the patent in so far as, in accordance with section 35 of the new law, he is relieved of the burden of proof that the patented article placed on the market is produced according to this patented process; in future, in suits for infringement of patent, the burden lies on the defendant to prove that the article in question was produced by another process than the patented one. The above provisions are still more sharpened by the fact that, according to the new structure of the law, not only those can be sued for damages who violate a patent knowingly, but also those who do so out of gross carelessness. All of these new provisions make it advisable that in interested industrial circles, and especially among small tradesmen, in future patented products should be handled with the greatest possible circumspection, with careful consideration of the

new provisions of law, in order to protect themselves against the disadvantages arising from a breach of patent.—*Board of Trade Journal.*

A NEW COMMERCIAL OIL.

A Chicago glucose company is now turning out 1,500 barrels per day of a new commercial product, which they call "corn oil." It is (says the *Shipping and Commercial List*) a yellow liquid much resembling linseed oil in appearance, and can be used in making paint, varnish, or soap. The oil is contained in the germinal part of the grain. In the process of manufacture the germ is separated from the kernel, and the oil obtained by hydraulic pressure. The oil has heretofore been a waste product, which was lost in the ordinary method of making starch and glucose. The proportion of oil in whole corn is about 4 per cent.—*Chemist and Druggist.*

BOARD OF TRADE RETURNS

SUMMARY OF IMPORTS.

	Month ending 29th February	
	1891.	1892.
Metals.....	£ 1,891,649	£ 1,752,223
Chemicals and dyestuffs.....	864,218	941,833
Oils.....	522,098	592,953
Raw materials for non-textile industries.....	2,180,652	2,413,257
Total value of all imports....	33,311,554	34,877,991

SUMMARY OF EXPORTS.

	Month ending 29th February	
	1891.	1892.
Metals (other than machinery)	£ 2,850,721	£ 2,629,389

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

2908. H. Salmon. Acid condenser and smoke arrester, the object of which is to clear the atmosphere. February 15.

3013. N. Hunting. Improvements in apparatus for distilling water in the presence of air, and for communicating heat thereto, and for supplying water and air thereto and delivering water therefrom. Complete Specification. February 16.

3042. R. Harrison. Improvements in and relating to means for heating or vaporising. February 16.
3215. C. Pryce. Improvements in kilns. February 18.
3708. F. H. Danchell. See Class XVI.
3834. E. G. Constantine. Improvements in or applicable to annealing and other furnaces. February 27.
4237. F. P. Hill, A. J. E. Hill, and W. Freeman. Adapting glass or earthenware bottles and vessels of a kindred nature for the purpose of containing hydrofluoric acid or compounds containing hydrofluoric acid. March 3.
4907. J. Lee and S. Lancaster. Apparatus for producing an atmospheric or Bunsen smokeless flame from liquid hydrocarbons as fuel. Complete Specification. March 12.
4911. T. O. Easton, A. Watt, and J. Buchanan, jun. Improvements in or appertaining to apparatus for filtering saccharine or other liquids and method of working the same. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.*

1890.

- 20,166. F. M. Robertson. Process and apparatus for evaporating and drying. March 16.

1891.

5342. H. L. Callendar. Electrical thermometers or pyrometers. March 2.
6057. W. H. Munn.—From G. Kaffenberger. Digesting apparatus. March 9.
6587. H. Hencke. Method and apparatus for drying and evaporating, suitable for use in breweries, distilleries, sugar and starch manufactories, and other industries. March 16.
7464. A. Hof. Carburating or carbonising apparatus. March 16.
7446. W. Birch. Apparatus applicable to the cleansing or filtration of sewage and other liquids. March 9.

1892.

154. A. T. Danks. Appliances for saturating air, oxygen, or other gases with the vapours of ether or other volatile fluids. February 24.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

3025. H. Axtmann. Apparatus for producing light by the combustion of magnesium or other highly luminiferous bodies. February 16.
3026. J. A. Dubbs. Improvement in the manufacture of asphaltum. Complete Specification. February 16.
3053. G. A. Fuels. Improvements in the manufacture of coal-dust brieks from bituminous coal, charcoal, coke, ore dross, brown coal, and the like. February 16.
3092. R. L. Barr, J. Macfarlane, E. J. Mills, and S. Young. Improvements in obtaining cyanides. February 17.
3305. O. Saporì. Improvements relating to the manufacture and utilisation of gas, and to apparatus therefor. Complete Specification. February 19.
3326. J. Addie and J. Cuninghame. Improvements in the treatment of spent lime and gas liquors and of blast furnace and other gases for the recovery of cyanides therefrom. February 20.
3355. E. W. Harding. Improvements in means or apparatus for the manufacture into blocks or moulded forms of carbonaceous matter for use as fuel. Complete Specification. February 20.

3442. J. B. Butler. Improvements in the manufacture of artificial fuel. February 22.

3619. T. Zohrab. An improved method of and apparatus for the treatment of peat and the conversion of peat into charcoal. February 24.

3959. J. Johnson.—From H. Kennedy, United States. Improvements in coke ovens. Complete Specification. March 1.

3981. J. Addie and J. Cuninghame. Improvements in the treatment of blast furnace illuminating and other gases, and of spent lime and gas liquors for the recovery of cyanides therefrom. March 1.

3995. A. J. Boulton.—From the Chicago Heat Storage Co., United States. Improvements in or relating to the manufacture of fuel-gas. Complete Specification. March 1.

4032. T. R. Osbourn. Apparatus for quenching coke. Complete Specification. March 1.

4033. T. R. Osbourn. Apparatus for the manufacture of coke. Complete Specification. March 1.

4041. I. S. McDougall and J. T. McDougall. Improvements in the treatment of mineral oils or spirits to facilitate the manufacture of gas therefrom. March 1.

4241. P. D. Ferriè and H. J. B. Thiroux. Improvements in apparatus for enriching ordinary gas by means of naphthalene. March 3.

4246. J. Woodward and F. W. Crossley. Improvements in apparatus for charging and discharging gas retorts. March 3.

4411. J. H. Parkinson. Improvements in the separation of oxygen, nitrogen, or other mechanically-mixed fluids, and obtainment thereof. March 5.

4440. C. Kilpatrick and The Ferriè Sewage and Water Purification Co., Lim. See Class X.

4556. A. Jones and E. Shepherd. Improvements in or connected with means or apparatus for consuming smoke and economising fuel. March 8.

4728. J. Moeller. Improved apparatus for making gas from oils, fatty substances, and other material. March 10.

4907. J. Lee and S. Lancaster. See Class I.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

- 19,888. J. Love. Manufacture of gas and apparatus therefor. March 9.

1891.

578. N. Bourgoïn and H. Decoree. Apparatus for making gas. March 16.

5960. B. J. B. Mills.—From E. L. Clarke. Machinery for the manufacture of peat fuel. March 9.

6947. W. T. Cotton and E. F. B. Crowther. Gas retorts. March 2.

7846. B. Egger. Automatic apparatus for indicating the presence in or absence from a space of gases of different specific gravity from the ordinary gaseous contents of such space. March 16.

- 21,223. W. R. Alpe. Apparatus for the manufacture of fuel blocks. March 2.

1892.

848. G. B. Field. Means for burning straw, cornstalks, and such like fuel. February 24.

965. W. E. Vickers and G. A. Everett. Machinery or apparatus for effecting the complete mixture of inflammable gas or vapour with air. March 2.

* See Note (*) on previous page.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

2953. C. D. Abel.—From The Actiengesellschaft für Anilin-Fabrikation, Germany. Manufacture of new bases and colouring matters therefrom. February 15.

3698. I. Roos. Manufacture of a new compound resulting from the reaction of a methylphenylhydrazine and salicylaldehyde. February 25.

3718. J. V. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in and relating to the manufacture and production of dyes derived from triphenyl-methane and of leuco compounds thereof, and of intermediate products in the said manufacture. February 25.

3791. A. J. Boulton.—From The Firm of W. Bruns, Germany. Improvements in the manufacture of colours specially applicable for colouring photographs. Complete Specification. February 26.

4109. A. Bang.—From G. A. Dahl, Germany. A new black azo dye-stuff, and the production of the same. March 2.

4110. A. Bang.—From G. A. Dahl, Germany. A black cotton dyestuff, combinations of the same, and processes for the production thereof. March 2.

4406. O. Imray.—From The Farbwerke vormals Meister, Lucius, und Brüning, Germany. Manufacture of beta-amido crotonic anilide and of beta-methylamido-crotonic anilide. March 5.

4407. O. Imray.—From The Farbwerke vormals Meister, Lucius, und Brüning, Germany. Process for the production of a red colour on textile fibres. March 5.

4677. P. Monnet. The manufacture of new colouring matters or dyes. Complete Specification. March 9.

4766. O. Imray.—From Messrs. Küchler and Buff, Germany. Process for the production of methylenediphenyl di-imide and its homologues and the conversion thereof into diamidodiphenylmethane and its homologues and into fuchsine. March 10.

4932. E. Geromont and H. Goldenberg. Improvements in the manufacture of colouring matters. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

3270. A. Fischesser. Process for producing azo colouring matters. March 2.

4871. B. Willcox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture of colouring matters derived from anthraquinone. March 16.

5984. B. Willcox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture or production of azo-colouring matters. February 24.

6376. Brooke, Simpson, and Spiller, Lim., and A. G. Green. Production of new bases and of azo-colouring matters therefrom. March 16.

6972. S. Pitt.—From L. Cassella and Co. Production of amidonaphtholsulpho acids and of dyestuffs therefrom. March 9.

7258. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture and production of dyes belonging to the rhodamine series, and of new materials for use in their preparation. March 9.

7713. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of diazo dyes, and of intermediate products in their preparation. March 16.

7963. O. Imray.—From The Farbwerke vormals Meister, Lucius, und Brüning. Manufacture of nitro- and amido-methyl-phenylpyrazolon and a derivative of the latter. March 16.

7964. O. Imray.—From The Farbwerke vormals Meister, Lucius, und Brüning. Production of blue colouring matters. March 16.

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

3210. A. Rowbotham. Improvements in the treatment of vegetable textile materials such as cotton, jute, and the like, for the purpose of deodorising, cleaning, and restoring the same, and in apparatus for use in connexion therewith, which improvements are also applicable to the treatment of sponges. February 18.

3268. R. Brown and J. C. Allardice. An improved composition for finishing linen and other fabrics. February 19.

3369. T. Thomson. Improvements in compositions for waterproofing paper, woven fabrics, and other materials. February 20.

3650. J. Clegg. An improved method for carbonising or extracting vegetable or other foreign matter from wool, woollen, or worsted fabrics. February 25.

3979. J. A. Wilson and D. Nicoll. Treating vegetable fibres either in the raw or in the manufactured state in order to arrest or retard decay. March 1.

4692. J. Villieus. A process for producing fibre from the hop plant for textile purposes or pulping. March 9.

COMPLETE SPECIFICATION ACCEPTED.

1891.

6698. J. G. Smith.—From F. Doller. Waterproofing textile materials. March 16.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

2939. A. Ophoven. Improved art or process or colouring pictures or textile fabrics. Complete Specification. February 15.

3413. C. Owens. An improved method of bleaching raw cotton or other vegetable fibres. February 22.

4278. H. Thies and E. Herzig. Improvements in bleaching. Complete Specification. March 4.

4823. C. J. E. de Haën. Improvements in or relating to the bleaching of vegetable and animal fibres or other organic substances. March 11.

COMPLETE SPECIFICATION ACCEPTED.

1892.

2096. W. Searle and W. H. Elliot. Apparatus for dyeing or chemically treating and drying paper, felt, or other fabrics. March 16.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

2991. J. J. Knight. Improved treatment of chloride of ammonium produced in the manufacture of soda by the ammonia-soda process to obtain carbonate of ammonia and chlorine. February 16.

3491. The Manchester Oxygen (Brin's Patent) Company, Limited, and W. M. Jackson. Improvements in the manufacture of carbonic acid. February 23.

3794. G. W. Sharp and C. H. Harvey. Improvements in or relating to converting ferrous chloride into ferric chloride, and in apparatus therefor. February 26.

3880. E. Rijn. Improvements in the manufacture of oxalic acid and cellulose. Complete Specification. February 27.

4346 P. E. Singer. Improvements in the manufacture of the hydrides of the metals of the alkalis. March 5.

4527. C. G. Collins. An improved process for the purification of brine. Complete Specification. March 8.

4657. H. C. Ball and G. W. Sharp. Improvements in or connected with the manufacture of ferric chloride. March 9.

4765. H. W. Crowther. Improvements in treating liquors containing sulphocyanides for the purpose of separating the said sulphocyanides therefrom. March 10.

4851. F. Ellershausen. Improvements in the manufacture of soda and potash. March 11.

4903. M. N. d'Andria. Improvements in the manufacture of sulphocyanides. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

4314. C. F. Claus. Manufacture of the aluminates, sulphates, and carbonates of soda and potash, and the production or recovery of alumina and other by-products. March 16.

4712. J. Pedder. Using a combination of sulphuric acid for the decomposition of chlorides, sulphides, sulphates, and of sulphuretted hydrogen. March 16.

6509. J. W. Wilson and C. H. G. Harvey. Treating waste liquor from galvanising works and other similar liquors to obtain ferric chloride. February 24.

8006. E. L. C. Martin. Manufacture of caustic soda and caustic potash. March 16.

8018. G. Lunge and J. Dewar. Process for the recovery of sulphur, carbonate of soda, and iron oxide from double sulphide of sodium and iron. March 2.

8844. A. F. M. L. Paillard. Manufacturing and regenerating salts of peroxide of iron. March 9.

17,130. F. Perez - Gutierrez. Process for moulding common salt (chloride of sodium) by melting it previously. February 24.

20,713. C. Kellner. Manufacture and production of chlorine and alkaline carbonates. February 24.

1892.

212. S. C. C. Currie. Improvements in the art of producing insoluble chlorides direct from the metals. March 2.

2389. L. Brunner and A. Zauner. Process for preparing at the same time neutral chloride of soda and precipitated phosphate of lime. March 16.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

3586. C. Armstrong. Improvements in kilns or ovens for burning and glazing sanitary ware and the like. Complete Specification. February 24.

3817. J. Hughes and C. Billington, jun. Improved construction of spurs, stilts, and thimble-pins for use in supporting pottery ware whilst being fired. February 27.

4525. H. D. Fitzpatrick.—From M. Schreiber and L. Ottinger, Germany. Improvements in the method of manufacturing glass bricks. Complete Specification. March 8.

4545. H. H. Pitt. Improvements in the process of the manufacture of pressed glass articles, and in apparatus therefor. March 8.

4585. F. Wright and C. Rawle. Improvements in the manufacture of articles of glass, and in apparatus therefor. March 8.

COMPLETE SPECIFICATION ACCEPTED.

1891.

21,997. J. K. Thompson. Fire-resisting bricks and material for lining, facing, or coating fireplaces, fireboxes, furnaces, ovens, and kilns of every kind. February 24.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

2957. H. Hartmann. Improvements in the manufacture of a resistible material, chiefly designed for building purposes. Complete Specification. February 15.

2970. E. Robbins. Improvements in buildings, structures, and decorative works, in vitreous, cementitious, and other materials, plant, and machinery therefor. February 16.

3079. C. R. Cowens. Improvements in or relating to the calcination of limestone, ironstone, or the like substances, and in the recovery and utilisation of by-products and residuals for commercial purposes. February 17.

3125. J. M. Bridson. An improved brick for building purposes. February 17.

3315. W. Thompson. Improvement in the method of calcining limestone. February 20.

3539. H. Brunson and E. W. Gillett. Improvements in building or paving blocks. Complete Specification. February 23.

4131. J. T. Knowles. — From Die Actiengesellschaft "Cimbria," Denmark. A process for the treatment of raw materials to be used in the production of Portland cement. March 2.

4149. W. H. Charlesworth. Improvements in slurry-drying structures used in the manufacture of cement. March 2.

4295. J. W. Ardin and J. Brown. An improvement in the construction of blocks or bricks for street pavements. March 4.

4408. C. J. Dobbs. Improvements in the manufacture of scoria or slag blocks for paving and other purposes. March 5.

4496. J. S. Holliday. Improved artificial stones. Complete Specification. March 7.

4499. J. Lyle. Improved combination of ingredients to form asphalt compounds, specially adapted for road and paving purposes generally. March 7.

4511. S. Turner. An improved fireproof floor. March 8.

4540. G. M. Graham. Improvements in building or paving blocks. Complete Specification. March 8.

4553. J. W. Knights. An improvement in burning Portland cement. March 8.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7184. W. W. Horn.—From W. L. Mason, T. W. Blakey, and J. A. Wright. Artificial stone. March 2.

10,137. H. H. Lake.—From H. B. Seely. Construction of floors. March 9.

22,198. F. H. Willis and R. Astley. Fireproof floor. March 16.

1892.

795. E. Websky. Treating gypsum casts. February 24.

1827. W. Brown. Method of jointing concrete paving. March 9.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

2927. H. Pidot. Improvements in the production of aluminium. February 15.

3024. A. G. Brookes.—From B. C. Molloy, South Africa. Improvements in precipitating and collecting metals from solutions containing them. February 16.

3090. A. D. Leyshon. An improvement in the process of coating tin and terne plates, and in apparatus therefor. February 17.

3237. R. A. Hadfield. Improvements in the manufacture of cast steel projectiles. February 19.

3308. M. N. d'Andria. Improvements in the recovery of hydrochloric acid and ferric oxide from ferrous chloride. February 19.

3422. A. E. Tucker and F. W. Harbord. Improvements in the linings of steel converters, Siemens and other metallurgical furnaces. February 22.

3493. R. L. Sentinella. An improved treatment of iron and steel for casting the same from crucibles. February 23.

3844. T. Twynam. Improvements in the separation of tin from tin scrap. February 27.

3854. T. M. Ash and H. W. Gill. Improvements relating to the depositing of metals. February 27.

3947. B. Talbot, sen. Improved form of furnace for iron and steel manufacture. March 1.

4173. P. Rossigneux. Improved method or means of desulphurising castings or alloys of certain metals. Date applied for, October 28, 1891, being date of application in France. Filed March 2.

4215. F. G. Fuller. Improvements in the extraction and recovery of gold and silver. March 3.

4333. F. Sugden and T. Sugden. Treatment of cast iron. March 4.

4334. J. Jones. Improvements in the manufacture of sheet iron. March 4.

4440. C. Kilpatrick and the Ferrie Sewage and Water Purification Company, Limited. A new or improved process for the utilisation of oxide of iron obtained as a by-product in the smelting or extraction of copper from cupreous ores, or from spent oxide obtained as a by-product in the purification of gas. March 7.

4460. W. P. Thompson.—From W. J. Miles, jun., H. S. Deming, and A. Herz, United States. Improvements in metallic alloys. Complete Specification. March 7.

4488. T. Evans and H. C. Bunkell. Improvements in amalgamating the precious metals and their ores, and the like, and in apparatus therefor. March 7.

4644. J. Nicholas. An improved means of extracting precious and other metals from their ores. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

3957. C. A. Faure. Manufacture or production of aluminium alloys. February 24.

5851. W. Sowerby and E. Casper. Casting metals. March 16.

6942. W. Beardmore. Manufacture of armour plates and apparatus therefor. March 2.

8083. L. Mond. Manufacturing nickel alloys. March 9.

8495. A. W. Warwick. Process for extraction of antimony from its ores, and separation of other metals therefrom. March 16.

9013. A. M. Clark.—From The Deutsche Gold und Silber Scheide-Anstalt, vormals Roessler, through Wirth and Co. Process for desilverising argentiferous lead. March 9.

9757. R. Heathfield. Process for coating or cleaning metals. February 24.

1892.

581. G. Pickhardt. Improvements in connexion with the use of aluminium and aluminium alloys. March 16.

1984. D. Dyrenforth. Manufacture or treatment of iron or steel. March 9.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

2913. G. Nahnsen. Improvements in the electro-metallurgic extraction of zinc. Complete Specification. February 15.

3114. C. Thompson. Improvements in electrical primary batteries. February 17.

3120. P. H. Bertrand. Improvements relating to galvanoplasties or the electro-deposition of metal. February 17.

3512. G. D. Davis. Improvements in the process of electrolysing alkaline salts. February 23.

3514. G. D. Davis. Improvements in the process of electrolysing alkaline salts. February 23.

3523. O. Imray.—From C. Wasmuth, Germany. Improved galvanic element. February 23.

3559. S. W. Kimble. See Class XIII.

3881. K. Kababka. Improvements in electrical accumulators. Complete Specification. February 27.

4103. R. Goodwin. Electro-deposition of aluminium on metals. March 2.

4154. E. Viarengo. Improvements in electric batteries. March 2.

4190. F. M. A. Laurent-Cely and E. Pinot. Improvements in electrical batteries. March 3.

4316. E. G. Hoffmann. Improvements in electric welding and in apparatus therefor. March 4.

4456. R. W. James.—From G. E. Gale, United States. A process for electro-plating. March 7.

4458. R. W. James.—From G. E. Gale, United States. An electrode for electro-plating. March 7.

4576. J. V. Sherrin. Improvements in secondary batteries. March 8.

4579. S. A. Rosenthal and J. V. Sherrin. Improvements in galvanic batteries and battery liquids. March 8.

4758. W. Boggott. Improvements in the method and means of obtaining electricity. March 10.

4768. S. W. Maquay. Improvements in electric batteries. March 10.

4820. L. Mereky. Improvements in primary batteries. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

2471. T. W. Bash and M. Doubleday. Manufacture of hydrolysed lead cells for electrical or storage batteries. March 9.

5167. F. E. Elmore and A. S. Elmore. Manufacture of tubes by electrolysis. March 2.

6243. S. M. L. Patz and R. Grebner. Galvanic batteries. February 21.

6247. J. V. Johnson.—From F. Gendron. Automatic regulating apparatus employed in connexion with galvanic batteries. February 24.

6793. P. C. E. Champion. The application of electricity for the production of pyrotechnic and other effects, applicable also for signalling and advertising purposes, and apparatus therefor. March 16.

7697. C. P. Eliason. Electrical accumulators or storage batteries. March 9.

8227. W. P. Thompson.—From H. O. Tudor. Electrodes for electric accumulators. March 2.

8845. R. Hadden.—From I. Cabanyes. Galvanic batteries. March 9.

1892.

1391. The London Metallurgical Co. and S. O. Cowper-Coles. Coating articles with a new metallic alloy by electro-deposition. March 2.

1484. J. B. Entz and W. A. Phillips. Secondary batteries. March 2.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

3239. C. H. Ridsdale. Improvements in lubricating with solid lubricants. February 19.

4174. J. Porteous. Improvements in the manufacture and preparation of soap or pieces of soap for sale or use. March 2.

4250. R. Zurrer. Improved process for transforming the unsaturated oleaginous fatty acids into less fusible saturated fatty acids. Filed March 3. Date applied for August 4, 1891, being date of application in France.

4447. O. Tilley. A new or improved cleansing composition and process of cleaning and purifying foul casks or barrels and the like. March 7.

4649. J. Gibson and C. Estcourt. Improvements in the manufacture of soap. March 9.

4883. H. Shaw. Improvement in the manufacture of soap. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

4451. R. Stone. Manufacture of soap and utilisation of the residue of the substances used therein. March 9.

7251. W. N. Hartley and W. E. B. Blenkinsop. Thickening oil. February 24.

21,438. C. L. Field. Manufacture of super-fatted soap. March 2.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

3142. H. Taylor. Improvement in the manufacture of paints and varnishes, also in materials for use of same. February 17.

3347. J. C. Margetson. A method of devulcanising vulcanised india-rubber, so as to recover raw rubber and the materials contained in the vulcanised rubber. February 20.

3559. S. W. Kinde. Improvements in the manufacture of compositions for insulating or other purposes. February 23.

4169. E. C. Williams, M. E. Williams, and C. May. Improvements in or relating to bronze or other metallic paints. March 2.

4252. D. Rigole. Improvements relating to the extraction of gutta-percha, and to apparatus therefor. Complete Specification. March 3.

4522. W. Thompson. An improvement applicable to blocks of laundry blue, black lead, and similar compositions. March 8.

4650. J. Gibson and C. Estcourt. Improvements in the manufacture of washing blue. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

5977. J. Robson. Preservative coatings for iron or other structures. February 21.

7036. G. Hand Smith. Treatment of gums and the preparation of varnishes therefrom. February 24.

8022. A. Honnan and B. Vulliez. Process and apparatus for the manufacture of white lead. February 24.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

3105. C. Cosinerie. Improvements in the manufacture of a light coloured albumen from blood. February 17.

4783. J. Pullman, W. R. Pullman, and A. Pullman. An improved process for treating skins and hides. March 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8796. B. Wright and D. Wright. Machinery or apparatus for staking, softening, and penehing leather. March 16.

1892.

951. L. Bertram. Process and apparatus for extracting glue or gelatin and grease out of hide and skin waste, and of bones at comparatively low temperature. February 24.

XV.—AGRICULTURE AND MANURES.

APPLICATIONS.

3029. H. H. Lake.—From the Biolytic Gypse Co., United States. An improved insecticide and fertiliser. Complete Specification. February 16.

3301. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. See Class XX.

3806. E. Groc and E. Ramond. A composition or dressing for vines and other trees. February 26.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8402. A. Knorre. Manufacture of artificial manure. March 16.

22,192. L. Lamattina. Conversion into manure of the refuse and foul matter from cities and towns. February 21.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

3241. A. G. Brookes.—From F. Paetow, Germany. Improvements in refining or purifying sugar. February 19.

3708. F. H. Danchell. Improvements in the cleaning and revivifying of charcoal in filters for saccharine juice, water, and other liquids, and in and connected with the construction of such filters. February 25.

COMPLETE SPECIFICATION ACCEPTED.

1891.

21,477. W. P. Thompson.—From J. Hirsch. Manufacture of cuhe, loaf, and similar sugar. March 2.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

3010. W. P. Thompson.—From C. F. Lawton, United States. Improvements in the process of manufacturing beer, ale, wine, cider, or the like. Complete Specification. February 16.

3011. W. P. Thompson.—From C. F. Lawton, United States. Improvements in the method of and apparatus for manufacturing beer, ale, wine, cider, or the like. Complete Specification. February 16.

3798. W. L. Wise.—From A. Antheaume, France. Improvements in the manufacture of beer. February 26.

3890. A. R. Waddell. A beverage. February 29.

4682. A. J. Boulton.—From The Pfaudler Vacuum Fermentation Co., United States. Improvements in the manufacture of beer. Complete Specification. March 9.

4688. A. J. Boulton.—From The Pfaudler Vacuum Fermentation Co., United States. Improvements in the manufacture of beer. Complete Specification. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7272. W. P. Thompson.—From A. H. Jacques. Apparatus for converting amylaceous substances into soluble products. March 9.

20,649. C. Hof.—From Schneider. Production of colour malt. March 16.

21,698. P. A. Attout, called Tailfer. Distilling and apparatus therefor. March 9.

1892.

1044. J. F. Henderson. Manufacture of unfermented wine. February 24.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

3377. H. H. Lake.—From La Société Mateu del Cano et Cie., France. Improvements relating to the preservation of meat. February 20.

3462. S. Pitt.—From J. Mariosa, Brazil. An improved process for the preservation of meat. February 22.

3470. G. E. Redfern.—From G. H. Neuhauss, J. F. H. Gronwald, and E. H. C. Oehlmann, Germany. Improvements in or applicable to apparatus for sterilising milk and other fluids. Complete Specification. February 22.

3592. P. McArdle. The preserving of fresh eggs. February 24.

4928. G. D. Sutherland. An improved food. March 12.

C.—Disinfectants.

3933. G. Kraemer. Process for the preparation of sulphonate salts from phenylised ethane derivatives and the preparation of disinfectants therefrom. February 29.

3977. S. Armitage and A. Gadot. An improved compound for disinfecting, deodorising, antiseptic, preservative, and similar purposes. March 1.

4205. W. Garthwaite. A new and improved method of disinfecting infected places, called a disinfecting smoke block. March 3.

COMPLETE SPECIFICATIONS ACCEPTED.

B.—Sanitary Chemistry.

1891.

4177. W. H. Watson. Means employed for the purification and decolourisation of water, dye, and other manufacturing refuse liquors, sewage, or other aqueous or saline liquids. March 2.

7466. W. Birch. See Class I.

8271. H. Whitley. Improved destructor furnace for refuse, and apparatus connected therewith. March 16.

22,531. W. Horsfall. Furnaces for destroying the refuse and dealing with the sewage, sludge, and other offensive material of towns. March 16.

22,747. J. T. Wood. A new or improved method or process for purifying sewage or foul water. March 2.

C.—Disinfectants.

1891.

17,421. H. B. Thornton. Manufacture of disinfectant tablets, blocks, or the like for use in water-closets, urinals, drains, and other places or articles. February 24.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

3091. J. Luke, jun. Improvements in and relating to the manufacture of paper. February 17.

3103. F. T. Jefferson. A new or improved manufacture of paper for the copying books of manifold writers for making tracings and for other like purposes. February 17.

3260. J. Luke, jun. Improvements in and relating to the manufacture of paper. February 19.

4973. P. Winterhoff. A new process for producing water or surface-marks in paper. March 2.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

826. R. Brown and G. Mackay. Paper-making machines for making the surface of the paper equal on both sides. February 24.

3061. J. Feirabend. Process for the manufacture of cellulose wadding. February 24.

20,224. T. Lumb. Machinery or apparatus for the manufacture of press papers, glazed boards, and the like. March 16.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

3147. A. Bang.—From G. A. Dahl, Germany. An antipyretic and anti-neuralgic chinolin derivative, and processes for the production of the same. February 18.

3301. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in, or means for the treatment of trees or plants for destroying caterpillars of *Liparis monacha* and other insects injurious to plant life. February 19.

3435. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture and production of pharmaceutical compounds. February 22.

3698. I. Roos. See Class IV.

4497. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of pharmaceutical compounds. March 7.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

6786. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture of hydrazine or diamidogen and its salts. February 24.

7026. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture of iodine substitution products of phenols and cresols. February 24.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

3500. E. Irelund. A new or improved method of producing coloured photographs. February 23.

3791. A. J. Boulton.—From W. Bruns and Co., Germany. See Class IV.

4498. J. Hauff. A process for developing photographic images. March 7.

COMPLETE SPECIFICATION ACCEPTED.

1891.

7312. W. W. J. Nicol. Photographic printing processes. March 2.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

3605. A. Broek. Improvements in material for fireworks. February 24.

3957. H. P. Merriam. Improvements in fuzes. Complete Specification. March 1.

4146. A. V. Newton.—From A. Nobel, France. Improvements in the manufacture of explosives. March 2.

4421. R. W. S. Griffith and G. H. Wadsworth. Improvements in the treatment of explosives. March 5.

4659. A. Philip. Improvements in the manufacture of nitro-glycerin. March 9.

4660. A. Philip. Improvements in the manufacture of nitro-glycerin. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7256. V. Alder. Manufacture of priming caps or exploders. March 16.

12,303. E. W. Anderson. Machinery for the manufacture of cordite and like explosives. March 16.

17,319. W. E. Fidler. Detonating fog-signalling apparatus, and detonators for use therewith for signalling on railways. March 16.

PATENT UNCLASSIFIABLE.

APPLICATION.

3475. J. E. Fletcher. The earno-preservative film. February 23.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 4.—VOL. XI.]

APRIL 30, 1892.

[Non-Members 30/- per annum; Members
21/- per Set of extra or back numbers;
Single Copies (Members only) 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, K.C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.

COUNCIL FOR YEAR ENDING JULY, 1892.

President: Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.

Vice-Presidents:

Sir Lowthian Bell, Bart., F.R.S.	Ludwig Mond, F.R.S.
Wm. Crowder	Dr. Hugo Muller, F.R.S.
James Duncan	B. E. K. Newlands.
Dr. John Evans, F.R.S.	J. C. Stevenson, M.P.
David Howard	A. Norman Tate.
S. H. Johnson	Sir John Turney.

Ordinary Members of Council:

A. H. Allen.	E. K. Muspratt.
Arthur Roake.	T. L. Patterson.
Jno. Calderwood.	Boverton Redwood.
Dr. Charles Dreyfus.	Jno. Spiller.
H. Grimshaw.	T. W. Stuart.
Prof. R. Meldola, F.R.S.	William Thorp, B.Sc.

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Dr. F. Hurter.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

A. H. Allen.	F. Hurter, Ph.D.
L. Archbutt.	C. C. Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Bernays, M.I.C.E.	Ludwig Mond, F.R.S.
H. Brunner.	B. E. K. Newlands.
E. Rider Cook.	John Pattinson.
W. Y. Dent.	W. H. Perkin, Ph.D., F.R.S.
Chas. Dreyfus, Ph.D.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	John Spiller.
D. B. Hewitt, M.D.	A. Norman Tate.
David Howard.	Wm. Thorp.
Prof. J. J. Hummel.	Thomas Tyrer.
Prof. A. K. Huntington.	

Editor:

Watson Smith, University College, London, W.C.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. John Evans, F.R.S., has been nominated to the office of President; and Professor J. Emerson Reynolds, F.R.S., has been nominated Vice-President under Rule 11.

Dr. F. Hurter, Dr. W. H. Perkin, F.R.S., Mr. John Spiller, and Professor T. E. Thorpe, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. Thos. Tyrer has been nominated an Ordinary Member of Council under Rule 17, in the place of Mr. John Spiller, nominated a Vice-President.

Mr. Ludwig Mond, F.R.S., has been nominated Foreign Secretary; and the Treasurer has been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18:—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in London on the 20th, 21st, and 22nd July next. An outline programme appears in this issue. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by MESSRS. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is prepared to offer 5s. apiece for copies of the Society's Journals for January 1883 in saleable condition.

LIST OF MEMBERS ELECTED, 22nd APRIL 1892.

Bradley, Fred. J., 52, Arboretum Street, Nottingham, light leather dresser.

Bull, Johannes C., Erith, Kent, chemical and mechanical engineer.

Croft, Arthur, 10, Abbey Street, Old Lenton, Nottingham, leather dresser.

Exley, Arthur, Meanwood Grove, Meanwood, near Leeds, tanner.

Farmer, Thos. H., 35, Oliver Street, Boston, Mass., U.S.A., pharmaceutical chemist.

Fischesser, Alfred, Lutterbach, near Mulhouse, Alsace, dye manufacturer.

Harvey, E. Feild, 1, Montpellier Square, Rutland Gate, S.W., chemist.

Horrocks, Wm. A., 8, Aldred Street, Crescent, Salford, bleacher and finisher.

Knecht, Dr. E., 239, Moss Lane East, Manchester, analytical chemist.

Little, Geo. A., 37, Moorland Avenue, Leeds, student.

Lowe, Jas. S., 1, Atholl Place, Edinburgh, sugar planter.

McElroy, Karl P., 1412, Sixteenth Street, N.W., Washington, D.C., U.S.A., agricultural chemist.

Morrell, Jno. B., Holdgate House, York, cocoa manufacturer.

Newall, John F., 8, Market Place, Manchester, merchant.

Preston, Edw. S., University College, Liverpool, civil engineer.

Terne, Dr. Bruno, 1512, South Sixth Street, Philadelphia, Pa., U.S.A., chemical works manager.

Torsell, Chas. T., McKees Rocks, Allegheny Co., Pa., U.S.A., chemist.

Townsend, Chas. W., Port Dundas, Glasgow, chemical manufacturer.

Townsend, Oliver C., Port Dundas, Glasgow, chemical manufacturer.

Whitehead, Cutell, 1114, New Hampshire Avenue, Washington, D.C., U.S.A., assayer to the U.S. Mint.

CHANGES OF ADDRESS.

Auer, Dr. H., 1/o Widnes; 71, Island Road, Garston, Liverpool.

Campbell, Colin M., 1/o Glasgow; c/o Long and Robertson, Habana, Mackay, Queensland.

Clark, R. Ingham, 1/o Park Prospect; 3, Albert Hall Mansions, Kensington Gore, W.

Clements, H. C., 1/o Putney; 79, Burton Road, Brixton, S.W.

Conrad, E. C., 1/o Holland; Portland Road, Gravesend.

Crawford, D., 1/o Alexandria; Kersal Vale Works, Higher Broughton, Manchester.

Crumbie, W. D., 1/o New York; 146, Washington Street, East Orange, N.J., U.S.A.

Davidson, J. E., 1/o Neweastle; 40, Percy Gardens, Tynemouth.

Freestone, J. W., 1/o New Ferry; 7, Wilton Road, Rock Ferry, Cheshire.

Galt, H. A., 1/o Philadelphia; c/o J. B. Ford Chemical Co., Wyandotte, Mich., U.S.A.

Gamble, J. C., 1/o Hardshaw Brook; Cowley Hill, St. Helens.

Garrett, F. C., 1/o South Shields; College of Science, Newcastle-on-Tyne.

Gibbs, W. P., 1/o Clydebank; Ely Paper Works, Cardiff.

Hart, Peter, 1/o Faulkner Street; c/o Tennants and Co., Chemical Works, Clayton, Manchester.

Henderson, Prof. G. G., 1/o The University; The Technical College, George Street, Glasgow.

Jackson, A. G., 1/o G.P.O.; Gotha Street, Valley, Brisbane, Queensland.

Jackson, R. Val., 1/o Hillhead; c/o Scotch and Irish Oxygen Co., Polmadie, Glasgow.

Joseland, W. H., 1/o Manchester; Talke, Stoke-on-Trent.

Laycock, Dr. W. F., 1/o Stowmarket; 2, Park Street, Dewsbury.

Lennard, F.; Journals to Enfield Lodge, St. John's Road, Blackheath, S.E.

Lindeman, Dr. G., 1/o Langereihe; Wilhelminenstrasse 1, H., St. Pauli, Hamburg.

Morris, Herb. N.; Journals to University Laboratory, Zurich, Switzerland.

Napier, J., 1/o St. Matthew's Place; 89, London Road, Ipswich.

Neilson, Thos., 1/o Kilmarnock; c/o Oregon Iron and Steel Co., Oswego, Oregon, U.S.A.

Richmond, H. D., 1/o Cairo; 50, Clanricarde Gardens, Bayswater, W.

Smith, H. Wood, 1/o Manchester; c/o May and Baker, Lim., Garden Wharf, Battersea, S.W.

Speakman, Jas., 1/o Cree Hill; Penhold P.O., Calgary, Canada.

Thornton, D. H., 1/o Bradford; Brookfoot Dyeworks, Brighouse, Yorks.

Trimble, Prof. H., 1/o Marshall Street; 145, North Tenth Street, Philadelphia, Pa., U.S.A.

Turner, H. B. H., 1/o Calcutta; 14, Jesus Lane, Cambridge.

Winsloe, H., 1/o Faulkner Street; c/o Tennants and Co., Chemical Works, Clayton, Manchester.

CHANGE OF ADDRESS REQUIRED.

A. E. Davies, 1/o 6, Rumford Place, Liverpool.

MEMBERS OMITTED FROM JANUARY LIST.

J. H. M. Fallon, c/o Peruvian Corporation, Lima, Peru.

D. Wesson, The American Cotton Oil Co., Guttenberg, N.J., U.S.A.

Death.

G. H. Makins, Danesfield, St. Albans.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: T. Tyrer.

Vice-Chairman: W. Crowder.

Committee:

C. F. Cross.	W. Ramsay.
J. Dewar.	B. Kechoud.
A. G. Green.	W. S. Squire.
S. Hall.	G. N. Stoker.
C. W. Heaton.	F. Napier Sutton.
D. Howard.	Wm. Thorp.
W. Kellner.	T. E. Thorpe.

Hon. Local Secretary: John Heron.

St. John's Villas, Worple Road, Wimbledon.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman*: Wm. Thorp. *Secretary*: John Heron. *Committee*: C. C. Hutchinson, B. E. R. Newlands, F. G. Adair Roberts, A. Gordon Salamon, T. Tyrer, and Frank Wilson.

SESSION 1891-92.

1892:—

May 2nd:—

Professor Wm. Ramsay, F.R.S., and Mr. J. C. Chorley. "The Distillation of Wood."

Dr. S. Rideal. "Notes on the Composition of some Indian Gums of known Origin."

May 30th:—

Mr. J. A. Nettleton. "Vinegar."

Dr. S. Rideal. "The Petroleum Jellies of Commerce."

June 13th:—

Professor V. B. Lewis. "Oil Gas."

Mr. Watson Smith. "The soluble Bituminous Constituents of certain Japanese Coals."—*cont.*

Meeting held Monday, 7th March, 1892.

MR. THOS. TYRER, IN THE CHAIR.

ON FLUID SPECIFIC GRAVITY DETERMINATION FOR PRACTICAL PURPOSES.

BY C. R. ALPER WRIGHT, D.S.C., F.R.S.

IN the practical determination of the "specific gravity" or "relative density" of a given fluid a very moderate degree of exactitude is often sufficient for the purpose in view; and in such cases various corrections and refinements may be safely omitted, which are simply *indispensable* when a higher amount of accuracy is desired. Thus when the value is only required to a degree of accuracy of three places of figures with a possible error of \pm one unit in the third place (*e.g.* when a liquid is found to have the sp. gr. 0.927, implying that the value lies between 0.926 and 0.928), corrections may be ignored that *must* be taken into account when 4, and *a fortiori* when 5, places of decimals are required; as when the specific gravity is said to be 0.9268, implying that it is between 0.9267 and 0.9269 or when it is said to be 0.92683, implying that it is between 0.92682 and 0.92684. For certain special technical purposes such high accuracy is requisite; in such cases the author has found certain modifications of the appliances ordinarily used, and various tables for corrections, of considerable practical use.

Before discussing these in detail it is as well to point out that in current technical literature the terms "density," "relative density," and "specific gravity" are frequently confounded together and used as though they were interchangeable, which strictly is by no means the case. By "density" is meant the *mass of a unit of volume*, a quantity not the same as the *weight of a unit of volume*. The former is independent of the gravitating force at the spot of observation; the latter not, being a quantity less by some 0.5 per cent. at the equator than at the pole, *ceteris paribus*. The "relative density" of a body A (as compared with another, B) implies the numerical value of the ratio between the density of A and that of B; if A and B are both examined at the same place (or at places where the force of gravity is the same) this ratio is identical with the ratio between the weight of a given volume of A and that of the same volume of B; but not otherwise. If B be some substance chosen as a standard, *e.g.* water (or hydrogen), when A is said to have such and such a "specific gravity," what is meant is that this value expresses the ratio of the density of A to that of the standard substance water (or hydrogen, &c.). If both A and B are at the same temperature, t , A is said to have the "sp. gr. at t " when the density of A is s times that of B, both being examined at t . If, on the other hand, the temperature of A is t_1 , different from that of B = t_2 , A is said to have the "sp. gr. at t_1 " when the density of A at t_1 is s times that of B at t_2 .

It results from the above that if $t_2 = 4^\circ \text{C.}$ and B be water, 1 grm. being the weight of 1 cc. of water at 4 at the place of observation, the value of s at $\frac{t_1}{4}$ is the weight in grammes of 1 cc. of substance examined at the temperature t_1 . If, on the other hand, t_2 be not 4, if d be the weight of 1 cc. of water at t_2 , the weight of 1 cc. of substance at t_1 is $s \times d$.

For various reasons it would be convenient to express all values relating to the relative density of bodies on the absolute scale of "weight per cc.," but inasmuch as the experimental data usually do not give this result without a little calculation, it is more frequently the practice to express the values either as "sp. gr. at t " or as "sp. gr. at t_1 ," where t (or t_2) is not 4°C. The result is that it is possible for different observers to obtain values apparently notably different through using different temperatures for the water of comparison, when really their results are identical. For instance, if a sample of vegetable oil at 20°C. is found by one observer to have the sp. gr. 0.92475 referred to water at 4° , by another the sp. gr. 0.92560 referred to water at 15.5° , and by the third the sp. gr. 0.92635 referred to water at 20° , it is impossible to say at sight whether these figures are sharply concordant or not; but if all three are reduced to "weight per cc.," it is obvious that they are identical; for the values of d for 4° , 15.5° , and 20° are respectively 1.00000, 0.99908, and 0.99827, and those of $s \times d$ respectively are—

$$0.92475 \times 1.00000 = 0.92475$$

$$0.92560 \times 0.99908 = 0.92475$$

$$0.92635 \times 0.99827 = 0.92475$$

The Pycnometer and Corrections Applicable thereto.

A pycnometer is a vessel so constructed that fluids can be poured therein so as to fill it to a sharply-defined level. Being weighed empty, and then filled to the given level with water and weighed again, the increment in weight represents the weight of water filling the instrument to the given level at the temperature obtaining = t . If again filled with another fluid also at t , the excess of weight over the empty vessel now represents the weight of the same volume of fluid. Calling the weight of water W , and that of fluid w , the value of $\frac{w}{W}$ is the "specific gravity of the fluid at t ," as above defined.

If, however, the water be weighed at t_1 , and the fluid at t_2 , the ratio $\frac{w}{W}$ will represent neither the sp. gr. at t

nor that at t_2 ; but will furnish an approximation to the value of the sp. gr. at $\frac{t_2}{t_1}$, which will be closer the less the vessel has altered in volume by expansion or contraction between t_1 and t_2 .

Usually the vessel is of glass, the coefficient of cubical expansion of which may be taken as $0.000025 = \frac{1}{40000}$ per 1°C. If $t_2 > t_1$ the volume of fluid contained is greater than that of the water by $\frac{t_2 - t_1}{40000}$ part of the latter. This is a quantity practically negligible when t_2 and t_1 do not differ much, even when four places of decimals are required; but if $t_2 - t_1$ have a considerable value, it is not negligible even when the specific gravity value is only required to be exact to within \pm one unit in the three places of decimals.

The following table indicates the correction to be subtracted for the over-estimation of w on account of the expansion of the vessel as the temperature rises from t_1 to t_2 (of course, to be added if $t_2 < t_1$):—

TABLE I.

$t_2 - t_1$	Correction to be subtracted.		
$^\circ \text{C.}$			
5	0.0025 per cent. of value	=	$\frac{1}{40000}$
10	0.005	"	$\frac{2}{40000}$
15	0.0075	"	$\frac{3}{40000}$
20	0.01	"	$\frac{4}{40000}$
30	0.015	"	$\frac{6}{40000}$
40	0.02	"	$\frac{8}{40000}$
50	0.025	"	$\frac{10}{40000}$
60	0.03	"	$\frac{12}{40000}$
70	0.035	"	$\frac{14}{40000}$
80	0.04	"	$\frac{16}{40000}$
90	0.045	"	$\frac{18}{40000}$
100	0.05	"	$\frac{20}{40000}$

Hence, if the water were weighed at 15° and the fluid at 100° , so that $t_2 - t_1 = 85^\circ$, the correction to be subtracted would be 0.2125 per cent. of the value; *i.e.*, for an oil, &c. of apparent sp. gr. 0.9535 at $\frac{100}{15}$ the correction would be -0.0020 , and for a heavier fluid of apparent sp. gr. 1.7385, -0.0037 ; quantities obviously affecting the third decimal place by more than one unit.

When the weights w and W are determined in air, the observed values are less than the true weights by an amount representing the weight of a quantity of air occupying a volume equal to the difference in bulk between the water or fluid and the counterpoising weights. These are generally of brass, about $8\frac{1}{2}$ times as heavy as water. Hence, the correction for "air buoyancy" to be applied to w and W is $\frac{15}{17} V a$, where V is the volume of fluid in cubic centimetres (practically, the weight in grammes of the water), and a is the weight of 1 cc. of air; a value varying with the temperature and pressure at the time of weighing, but for an average temperature of 15.5°C. , and average pressure of 760 mm., having the value 0.001223; whence $\frac{15}{17} a = 0.001079$.

If the pycnometer hold V cc. of fluid, the true specific gravity is consequently not $\frac{w}{W}$, but $\frac{w + V \times 0.001079}{W + V \times 0.001079}$. When w and W are nearly the same (specific gravity near unity), this correction may be ignored, as also, in most cases, when only three places of decimals are required; if, however, four are desired, the following table gives sufficiently nearly the relations between these two fractions:—

TABLE II.

Value found for $\frac{10}{W}$	Correction to be added.
0.25	+ 0.0008
0.5	+ 0.0005
0.75	+ 0.0003
1.0	Nil.
1.25	- 0.0003
1.5	- 0.0005
1.75	- 0.0008
2.0	- 0.0011
2.25	- 0.0014
2.5	- 0.0016
2.75	- 0.0019
3.0	- 0.0022

When five places of figures are required, it is not sufficient to take the mean value of a for 15.5°C ., and 760 mm. as above; but the appropriate value for each case must be taken from the following table; *e.g.*, for 20° and 730 mm. $a = 0.001157$; for 10° and 770 mm. $a = 0.001263$, and so on.

TABLE III.

Temp.	730 mm.	740 mm.	750 mm.	760 mm.	770 mm.

30	0.001119	0.001134	0.001149	0.001165	0.001180

Modified Pyknometer.

Certain forms of pyknometer in common use (specific gravity bottle with perforated stopper, with or without internal thermometer, Sprengel U-tube, &c.) have the disadvantage that if the temperature of the balance is above that at which the instrument is filled, expansion is apt to take place whilst weighing, so that the liquid runs over, and if volatile is partly lost. Moreover, with all such forms, to make valuations at different temperatures, a fresh weighing must be made for each temperature.

The following modifications of the ordinary long-necked flask with a mark on the stem have been found by the author extremely serviceable not only in obtaining values exact to five places of figures, if requisite, but also in avoiding the above inconveniences and in obtaining a series of valuations at different temperatures with comparatively little trouble.

Figs. 1 and 2 represent two varieties; the first is conveniently constructed by sealing up the lower end of an

Fig. 1.

Fig. 2.

ordinary pipette (10, 25, 50, or 100 cc.), and etching a millimetre scale on the stem. For weighing, this is supported by wire holder, Fig. 3, hung on to the hook of

Fig. 3.

Fig. 4.

the balance. The second is a flat-bottomed flask with two necks: one a long narrow tube with millimetre scale, as before; the other, a ground tubulus, into which a stopper fits provided with a thermometer for reading off the temperature of the contents of the flask. This form is especially convenient for cleansing and re-filling, the second neck allowing air to enter in a way impracticable with the first form, especially with small-sized instruments.*

In order to standardise the instrument for all purposes, it is requisite to know the quantity of water contained when filled up to a given level at a given temperature, and to have the means of thence calculating the quantity contained when filled up to any other level at any other temperature. This is effected by determining the quantity of water

* The construction of a ground stopper with a thermometer passing through (fused, not cemented) is a rather delicate piece of workmanship. The instruments exhibited by the author were made for him by Messrs. Negretti and Zambra, Holborn Viaduct.

contained at a given standard temperature when filled up to the commencement of the scale, and the further quantity of water corresponding to each millimetre of the scale. If the first quantity be w , and the second a , the quantity of water contained when filled up to a level of n millimetres on the scale, W_n , is given by the formula—

$$W_n = w + n a.$$

In order to deduce the variations in the value of W_n with different temperatures, a special table is employed, described below.

To determine the constants w and a , the empty vessel is weighed (noting the temperature and pressure in order to obtain data for the air-buoyancy correction), and water poured in to a convenient level, a little above the commencement of the scale. The instrument is then immersed in a large pan of water provided with a stirrer and thermometer, the temperature being slightly below that at which the standardising is to be effected. When the temperature of the bath is obtained, and the level of the water in the pyknometer does not alter, the level and temperature are read off. The bath is slightly raised in temperature by pouring in a little warm water, well stirred, and the process repeated, and so on until the series of temperature readings averages the required standard amount; then the average of the level readings is the level for that temperature. The instrument is wiped dry and weighed again, so that the weight of water contained up to that level at the standard temperature is known. More water is now poured in, and the rise of level carefully noted, also the increment in weight. This operation is repeated at different parts of the scale, so as to obtain various valuations of a .

Thus, with a particular instrument, the following data were obtained, the scale being 30 millimetres long; mean temperature reading, 15.5°C ; mean level for that temperature, 4.6 millimetres; weight of water contained (weighed in air at 15 and 758 millims. pressure), 50.573 grms. Further weighings on calibrating the tube:—

Rise of Level.	Weight of Water added.	Water per Millimetre.
From 1.5 to 28.1	1.205	0.0453
From 1.3 to 19.8	0.833	0.0452
From 15.1 to 28.9	0.627	0.0454
Mean value of a		0.0453

Obviously the bore of the tube was sensibly uniform at both top and bottom of scale.

Water contained (in air) up to 4.6 millimetres ...	50.573
Subtract 4.6×0.0453	0.208
Value of w (in air)	50.365

The correction for air buoyancy is—

$15 \times 50.3 \times 0.001223 = 0.054$ gram; whence the value of w (corrected to vacuum) $= 50.365 + 0.054 = 50.419$.

Hence, when filled up to a level n millimetres with water at the standard temperature 15.5° , the weight of water, W_n , contained is—

$$\begin{aligned} \text{In air} \dots W_n &= 50.365 + n \times 0.0453 \\ \text{In vacuo} \dots W_n &= 50.419 + n \times 0.0453 \end{aligned}$$

When high accuracy is required, several valuations of W_n should be thus made, and averaged.

The instrument being thus standardised, if it be required to determine the specific gravity of a fluid at T° where T is the temperature of standardising and T° some other temperature, all that is necessary is to determine the weight w_n of fluid that fills up the pyknometer to the level n

millimetres at the temperature T° ; then the value required is approximately given by the formula—

$$S = \frac{w_n}{W_n}$$

To obtain the exact value, this result must be corrected by means of Table I. (*supra*), so as to allow for the variation in capacity of the vessel between T° and T° . Of course W_n is corrected to vacuum if w_n is so corrected and not if the air-weighing only is taken.

In order to find the value of w_n exactly the same process is gone through as in the case of standardising the instrument: the pyknometer, filled with fluid, is placed in a bath of water at a temperature a little below T° ; the level being read, the temperature is slightly raised, and a new pair of readings taken, and so on until the mean of the temperature readings is T° . When desired, a whole series of valuations can thus be made for mean temperatures T_1, T_2, T_3, \dots only one weighing of the fluid being requisite throughout. By using a pyknometer holding 50 or 100 cc., weighing to half a milligramme, and using several level and temperature readings for averages in each case, and finally correcting by means of Table I., valuations of specific gravity at T_1, T_2, T_3, \dots &c. can be readily obtained with comparatively little trouble, exact to within ± 0.00001 , or at most ± 0.00002 (\pm one or two units in the fifth decimal place).

For example, using the 50 cc. pyknometer above described as illustration, the following figures were obtained with a sample of vegetable oil:—

Weight in air * of contained oil $w_n = 48.763$.

Reading on Min. Scale.	Corresponding Temperatures.
7.9	19.1
8.7	20.1
9.2	20.8
—	—
Average 8.6	Average 20.0
11.9	24.5
12.2	25.0
12.6	25.5
—	—
Average 12.23	Average 25.0

Weight in air of water filling up to 8.6 mm. at 15.5° :
 W_n (at 15.5°) $= 50.365 + 8.6 \times 0.0453 = 50.755$
 Weight in air of water filling up to 12.23 mm. at 15.5° :
 W_n (at 15.5°) $= 50.365 + 12.23 \times 0.0453 = 50.919$

$$\text{Uncorrected sp. gr. at } \frac{20}{15.5} = \frac{w_n}{W_n} = \frac{48.763}{50.755} = 0.96075$$

Correction from Table I.: 4.5° temperature difference represents -0.01125 per cent. $= -0.00011$

$$\text{Corrected sp. gr. at } \frac{20}{15.5} \dots \dots \dots = 0.96064$$

$$\text{Uncorrected sp. gr. at } \frac{25}{15.5} = \frac{w_n}{W_n} = \frac{48.763}{50.919} = 0.95766$$

Correction from Table I.: 9.5° temperature difference represents -0.02375 per cent. $= -0.00023$

$$\text{Corrected sp. gr. at } \frac{25}{15.5} \dots \dots \dots = 0.9574$$

* The specific gravity being not much below unity, the correction for air buoyancy is negligible when only four places are required, only affecting the fifth decimal place by a few units (*vide* Table II., *supra*).

Hence, taking values to four places only, 0.9606 and 0.9574 are the specific gravities of the oil at 20° and 15.5° respectively.*

TABLE IV.

T = Temperature.	D = Weight of 1 cc. of Water.	1 + $\frac{T - 4}{10000}$	D × $(1 + \frac{T - 4}{10000})$	Difference per 1°.

100	0.9586	1.00240	0.9599	- 0.00076

When it is required to determine the specific gravity of a fluid at some temperature T° different from that at which the instrument is standardised (i.e. referred to water *also* at T°), the following table enables the weight of water W_{HT} contained at T° up to any given level in millimetres, to be deduced from the weight W_n contained at the standard temperature. The first column gives the temperature T° ; the second the relative density of water at that temperature with respect to water at 4° C. as unity (or otherwise, the weight of 1 cc. of water at T°); the third the capacity at T° of a glass vessel holding 1 cc. at 4° ; and the fourth the products of the corresponding numbers in the third and fourth columns representing the relative weights of water contained at the various temperatures. If a be the tabular

* From these figures the rate of expansion of the oil between 20° and 25° is deducible, 95743 volumes at the lower temperature becoming 96061 volumes at the higher temperature; whence 100 volumes at 20° expand to 100.335 at 25° , i.e. the oil expands 0.067 per cent. in volume per 1° . Or the increment in bulk may be directly deduced from the readings; thus—

Rise of fluid in stem on heating from 20° to $25^{\circ} = 12.23 - 8.6$, or 3.63 mm., corresponding with $3.63 \times 0.0453 = 0.164$ cc. Fluid occupies about 50.7 cc.; expansion of glass through 5° consequently represents an increased capacity of about $50.7 \times \frac{5}{40000} = 0.006$ cc.

Hence, total increment in volume is $0.164 + 0.006 = 0.170$ cc. = 0.034 cc. per 1° , representing $\frac{100}{50.7} \times 0.034 = 0.067$ per cent. expansion per 1° , as before.

The modified pycnometer is, in fact, a form of dilatometer.

number in the fourth column corresponding with T° , and b that corresponding with the temperature at which the instrument is standardised, t , then

$$W_{HT} = W_n \times \frac{a}{b}$$

To determine the specific gravity at T° , it is simply requisite to determine, as before, the weight W_1 of substance filling the pycnometer to the level n millimetres at the temperature T° ; then the sp. gr. S is given by the formula—

$$S = \frac{w_n}{W_{HT}} = \frac{w_n}{W_n} \times \frac{b}{a}$$

Thus in the case of the preceding example of vegetable oil, suppose that it is required to determine the specific gravity at 20° , and also at 25° , from the data given. The instrument being standardised at 15.5° , the value of b from the table is 0.99936; similarly for 20° , $a = 0.99867$; and for 25° , $a = 0.99766$. At 20° (when the fluid stands at 8.6 millimetres) $w_n = 48.763$ and $W_n = 50.755$, whence—

$$\text{specific gravity at } 20^{\circ} = \frac{48.763}{50.755} \times \frac{0.99936}{0.99867} = 0.96141.$$

At 25° (when the fluid stands at 12.33 millimetres) $W_n = 50.919$, whence—

$$\text{specific gravity at } 25^{\circ} = \frac{48.764}{50.919} \times \frac{0.99936}{0.99766} = 0.95929.$$

When it is required to calculate the weight of fluid per cubic centimetre at any given temperature, if the specific gravity of the fluid at that temperature be known ($= S$) with reference to water at any given temperature (the same as the fluid, or different) $= T^{\circ}$, the weight of 1 cc. is given by the formula—

$$\text{weight of 1 cc.} = S \times D,$$

where D is the value in the second column of the above table corresponding with the temperature T° .

Thus the oil possessing the sp. gr. 0.95929 at 25° , and 0.96141 at 20° , will weigh—

$$0.95929 \times 0.99711 = 0.95652 \text{ grms. per cc. at } 25^{\circ}$$

$$0.96141 \times 0.99827 = 0.95975 \text{ grms. per cc. at } 20^{\circ}$$

As above explained, this mode of expressing results (weight per cc. at a temperature T°) is far preferable to any other method for relative density valuations.

Immersion Method and Corrections applicable thereto.

A heavy suspended body (conveniently a glass plummet) is weighed in air and then when immersed in the fluid to be examined at a temperature t_1 ; similarly it is weighed in water at t_2 ; if W_1 be the weight in air, W_2 in the fluid, and W_3 in water, the ratio of the losses of weight experienced when weighed in the two fluids $\frac{W_1 - W_2}{W_1 - W_3}$ gives an approxi-

mation to the relative density at t_1 ; from which the true value is obtained by subtracting a correction for the alteration in volume of the plummet between t_1 and t_2 . When the plummet is of glass this correction is obviously identical with that applying in the case of a glass pycnometer, and may accordingly be deduced from Table I. *supra*.

Precisely the same correction for air buoyancy applies in the determination of the values $W_1 - W_2$ and $W_1 - W_3$ as in the case of the pycnometer; hence, when only four places of decimals are requisite, the correction may be deduced from Table II.; and when five are required, by means of Table III.

When the weight of water displaced by the plummet has been determined for some one temperature, that displaced at any other temperature is calculable by means of Table IV., precisely as in the case of the contents of a hollow glass vessel, the tabular values taking into account both the expansion of the glass and the diminution in density of water with rise of temperature.

When results accurate to \pm one unit in the fourth or fifth decimal place are required, it is indispensable that the weighing should be made by means of an accurate chemical balance; but when only three places are required,

"hydrostatic balances" on the steelyard principle (*e.g.* Westphal's) are sufficiently accurate for the purpose. Such instruments as sold are often sufficiently delicate to yield concordant figures to four places; but the results obtained with different instruments often show differences considerably exceeding the limits of variation of any one of them. With any given instrument of fairly good construction, figures accurate to within \pm one or two units in the fourth decimal place (*e.g.* giving the value 0.9264, implying something between 0.9262 and 0.9266 or between 0.9263 and 0.9265) may be readily obtained by constructing a table of errors for the instrument by carefully comparing the results obtained therewith and with a delicate pycnometer, using the same fluids at the same temperature for each, and applying the corrections from Tables I. and II. when necessary. This involves a good deal of trouble; but unless an instrument has been thus checked it is never safe to rely on its indications beyond the third place of decimals. When, however, only three places are required, a hydrostatic balance is an extremely convenient instrument, especially for observations at higher temperatures, *e.g.*, near 100° C.

Aerometric Method.

Aerometers (hydrometers) as generally sold are instruments decidedly wanting in precision, excepting when prepared for certain special purposes, *e.g.* alcoholometry; so that their indications are rarely exact within less than \pm one or two units in the third decimal place. Moreover, the uncertainty as to the exact level of the liquid, owing to the curvature of its surface through adhesion to the stem, often prevents any extreme degree of delicacy being attainable. Unless the liquid is very dark coloured the level is best read off as with a burette, the lowest point of the meniscus of the upper surface of the liquid being viewed horizontally against the stem of the hydrometer.

With hydrometers as ordinarily sold it results from the nature of the graduation that no means exists of accurately checking the indications at different parts of the scale, excepting the rather tedious process of preparing a series of fluids of different densities, reading off the hydrometer levels therein at a standard temperature, and determining carefully the true specific gravities of the various fluids at that temperature by means of an accurate pycnometer carefully handled. A much simpler plan the author finds is to construct a table for the instrument by means of a few easily-made readings for the determination of a certain constant, by means of which the specific gravity of a liquid can be readily known with an accuracy of about ± 0.0001 or ± 0.0002 (± 1 to 2 units in the fourth decimal place). To effect this the ordinary hydrometer graduations are abolished, and instead a simple divided scale (conveniently of millimetres) etched on the stem.

The valuation of the constant k to be determined for such an instrument is arrived at as follows: The hydrometer is floated in a fluid of such specific gravity D_1 at the standard temperature that nearly the whole of the graduations of the stem are above the surface (in the case of an instrument intended for specific gravity values less than 1.0 the fluid may be water). The reading on the scale representing the level of the fluid is then carefully noted as the *zero point* of the instrument. A suitable weight w is then attached to the top of the stem,* and the level of the surface again read off. Let l be the difference between the two readings, *i.e.* the additional length of stem now immersed; and let W be the weight of the hydrometer (without the additional weight w); then—

$$k = \frac{w}{W l}$$

* It sometimes happens that attaching an extra weight at the top outside the fluid prevents the hydrometer from floating properly upright, and so interferes with the sharpness of the readings; this is more especially not to occur with the modification, described below, where the scale is on the jar, and the reading taken by means of a ring etched on the hydrometer like an Erdmann float. In such cases it suffices to attach to the lower bulb of the hydrometer by means of wire, a bit of brass or lead, or a lump of glass, the weight of which, together with the wire, has been previously ascertained to be w , when weighed immersed in the standard fluid.

To determine the relative density D_2 of a second lighter liquid in terms of that of the first (*i.e.* to determine the value of $\frac{D_2}{D_1}$) the hydrometer is floated in the second liquid at the standard temperature and the level to which it sinks noted. If the difference between this point and the zero point be n millimetres (*i.e.*, in the instrument sink so that the zero point is immersed n millimetres below the surface); then—

$$\frac{D_2}{D_1} = \frac{1}{1 + n k}$$

The following table gives the values of $\frac{1}{1 + n k}$ over a considerable range when the product $n k$ is known.†

$n k$	$\frac{1}{1 + n k}$	Difference.	$n k$	$\frac{1}{1 + n k}$	Difference.

Instead of having the millimetre scale engraved on the stem of the hydrometer, it may be etched on the jar itself, a ring being also engraved on the belly of the hydrometer like an Erdmann float (Fig. 4). The readings are then taken by reading the level of the meniscus of the fluid surface on the millimetre scale, and also that of the ring; the difference between the two when the hydrometer floats in the standard liquid at the standard temperature is carefully noted, representing a second constant for the particular instrument = a millimetres. When the hydrometer floats

† The above formula is arrived at thus:—Let L be the "equivalent length" of the hydrometer with respect to the first liquid, *i.e.*, the length of a column of that liquid of section equal to that of the hydrometer stem (considered uniform) that would weigh W at the standard temperature.

Then—

$$L : L + l :: W : W + w$$

Whence—

$$L = \frac{W}{w} l$$

And—

$$k = \frac{1}{L} = \frac{w}{W l}$$

Again—

$$D_2 : D_1 :: L : L + n$$

Whence—

$$\frac{D_2}{D_1} = \frac{L}{L + n} = \frac{1}{1 + n \times \frac{1}{L}} = \frac{1}{1 + n k}$$

in the second liquid, the corresponding difference of readings is noticed = d . Then $d - a = n$ in the preceding formula.

The advantage of this form of instrument is that whereas only one reading is practicable when the scale is engraved on the hydrometer stem and the instrument floated in a fluid, any number of different pairs of readings can be taken and averaged for higher accuracy when the scale is etched on the jar. When one pair of readings (meniscus and ring) has been taken, a few drops more liquid are carefully added to the contents of the jar, or pipetted out of it, thus furnishing two different level readings, and consequently a second valuation of their difference; and so on as often as may be desired.

In making these various readings it is convenient to vary the temperature slightly (e.g. by immersing the jar in a large beaker of water), so that the average of the various temperature readings may be that required, precisely as with the modified pycnometer above described.

The level of the meniscus at the top of the fluid can be read somewhat more accurately by constructing the jar of a U shape, each limb having a millimetre scale etched upon it. One limb is made wide enough to enable the areometer to ride freely therein, the scale being sufficiently prolonged to take in all possible positions of the ring etched on the hydrometer; the other may be narrower, but should be sufficiently wide to prevent any errors through varying capillarity with different fluids. On this limb a shorter scale suffices, as the meniscus of the top level only is read thereon. Of course each scale commences at the same horizontal level, so that the difference between the readings (meniscus in narrower limb, ring in wider limb) represents the depth of the ring below the surface.

The following figures illustrate the modes of standardising and use of the millimetre jar areometer. The same jar was used throughout; the weighings were *not* corrected for air buoyancy.

Areometer A; intended for fluids of sp. gr. 1.000 to 0.850:—

Weight of areometer, W	26.077 grms.
Additional weight, w	3.548 "
Depth of ring below meniscus when immersed without additional weight in distilled water at 15.5° (average of 8 concordant readings) = a	47.76 mm.
Do. do. with additional weight = b	135.76 "

Hence $l = b - a = 88.00$ mm.

$$\text{and } k = \frac{w}{W \times l} = \frac{3.548}{26.077 \times 88.00} = 0.001546 "$$

Areometer B; for liquids of sp. gr. 1.000 to 0.900:—

$W = 59.846$ grms.
$w = 3.548$ "
$a = 109.4$ mm.
$b = 183.3$ "

Hence—

$$l = 183.3 - 109.4 = 73.9 \text{ mm.}$$

and—

$$k = \frac{3.548}{59.846 \times 73.9} = 0.0008022$$

Areometer C; for liquids of sp. gr. 1.850 to 1.600:—

$W = 106.561$ grms.
$w = 8.088$ "

Depth of ring below meniscus when immersed at 15.5° without additional weight in sulphuric acid of specific gravity at 15.5° 1.83538 (determined by pycnometer) = a 59.02 mm.

Do. do. with additional weight $w = b$ 151.01 "

Hence—

$$l = 151.01 - 59.02 = 91.99 \text{ mm.}$$

and—

$$k = \frac{8.088}{106.561 \times 91.99} = 0.0008251$$

Determination of Specific Gravity at 15.5° of Diluted Alcohol with Areometers A and B.

Areometer A. Depth of ring below meniscus when immersed in liquid at 15.5° (average of several readings) = d 76.29 mm.
 Ditto when immersed in water (*supra*) = $a = 47.76$ mm.

Then—

$$n = d - a = 76.29 - 47.76 = 28.53$$

and—

$$nk = 28.53 \times 0.001546 = 0.04411$$

From the table the corresponding value of $\frac{1}{1+nk}$ is 0.9578, i.e., the specific gravity at 15.5° is 0.9578.

Areometer B. Mean value of d at 15.5° ... 164.0 mm.

Value of a (*supra*) ... 109.4 "

Hence—

$$n = d - a = 164.0 - 109.4 = 54.6 \text{ mm.}$$

and—

$$nk = 54.6 \times 0.0008022 = 0.04380 \text{ mm.}$$

From the table the corresponding value of $\frac{1}{1+nk}$ is 0.9581.

Valuations of the same fluid with three different modified pycnometers as above described gave the following results at 15.5°:—

No. 1. Pycnometer of pattern shown in Fig. 1, holding about 100 cc.	0.95791
No. 2. Another pycnometer of pattern shown in Fig. 1, holding about 25 cc.	0.95786
No. 3. Pycnometer of pattern shown in Fig. 2, holding about 100 cc.	0.95789
	<hr/>
	0.95789

In similar fashion, the following figures were obtained with a sample of stronger alcohol:—

Areometer A. $n = 83.07$ mm.

Hence—

$$nk = 83.07 \times 0.001546 = 0.1284.$$

Corresponding specific gravity value from table 0.8862.

No. 3. Value found with pycnometer No. 3 *supra* 0.88624

No. 4. Pycnometer of pattern shown in Fig. 1, holding about 50 cc. 0.88623

Determination of Specific Gravity at 15.5° of Slightly Diluted Oil of Vitriol.

Areometer C. Depth of ring below meniscus

at 15.5° = d 143.68

Value of a (*supra*) 59.02

Hence—

$$n = d - a = 84.66$$

and—

$$nk = 84.66 \times 0.0008251 = 0.06985$$

The value of $\frac{1}{1+nk}$ corresponding to this from the table is 0.9347; whence, since $D_1 = 1.83538^*$ the specific gravity of the acid, D_2 at 15.5° is—

$$D_1 \times \frac{1}{1+nk} = 1.83538 \times 0.9347 = 1.7155$$

Value found with pycnometer No. 1 (*supra*) ... 1.71568

" " No. 4 1.71563

DISCUSSION.

MR. DAVID HOWARD said that for those who really wished to make industrial chemistry a scientific matter, Dr. Wright's paper was of extreme value. Every chemist, whatever his qualifications, was under the impression that he could take a specific gravity. But if the determinations made were compared with those of others, it would be seen

* The value for D_1 at 15.5° was found to be—

By pycnometer No. 1	1.83539
No. 1	1.83537
Mean	1.83538

that men of ability, careful manipulators and observers, differed to an astonishing degree. It was the minute details which Dr. Wright had insisted upon, which should be carefully investigated. If chemists wished to keep pace with the times, they were bound to make sure that their observations were of real accuracy. No instrument could be trusted until it had been tested; and no determination could be relied upon until the scientific values, as well as the mere mechanical values, had been fully considered.

Mr. ARNOLD PHILIP said that he had recently had occasion to take the specific gravity of a sample of petroleum residue at a temperature near 100°C . This he had done in the usual manner by means of a Sprengel's tube, and in calculating out the results he had been inclined to think that some correction should be applied for the actual alteration of the internal cubical capacity of the tube, due to the alteration of form on heating. The usual correction for the cubical expansion of glass, which Dr. Wright had mentioned, would, of course, be absolutely all that was necessary if one were dealing with a solid mass of glass, but if one were employing a hollow vessel, it was difficult to imagine that no internal distortion of form occurred on raising the temperature through from 70° to 80°C . If such distortion did take place, it seemed difficult to make a correction for it. What he imagined would be the best method, would be to weigh the vessel full of mercury (or some other pure fluid of high boiling point, whose coefficient of expansion was accurately known) at 100°C ., and calculate out the volume which the weight of mercury thus obtained should occupy at this temperature. He would be glad if Dr. Wright would elucidate this difficulty, and point out to the meeting the most simple method of making such a correction if it were necessary.

Dr. MURRAY THOMSON insisted on the necessity for the greatest accuracy in taking specific gravities. The author had suggested many necessary corrections, but there was one point which, though not mentioned, could hardly have been overlooked, and that was the narrowness of the vessel used with the hydrometer. It was well known that in using an instrument of that kind it was almost impossible to avoid producing friction against the side of the vessel. All the methods for eliminating such friction were more or less apt to fail; and the only way out of the difficulty was to make a great number of determinations, and take the mean of them. Again, in introducing the specific gravity instrument into a liquid, one was apt to find air bubbles adhering to the sides of the apparatus, though almost invisible to the eye. This effect could only be avoided by holding the instrument up and down in the liquid—thus leading to another inaccuracy.

Mr. OSCAR GUTTMANN said that he was much interested in the determination of the expansion of liquids at increasing temperatures which he might call the inverse of the specific gravity. In a factory with which he was connected, specific gravity calculations were made every day by the dozen. These determinations were made with the very best instruments obtainable, and as much care as possible was taken; yet he would like to say that he had learned from Dr. Wright a great deal in regard to the matter of taking an accurate specific gravity. But he would like to know whether in the instrument proposed by Dr. Wright, supposing it was adjusted for 15°C . and a liquid was poured into it at 100°C ., the glass cylinder would not be likely to expand. As the divisions were already spaced off on the glass cylinder, the instrument would by the expansion of the glass (which he thought was very likely to happen) then, very probably, be inaccurate, and it might be necessary to have different cylinders for different temperatures. He had noticed the very same thing when determining the expansion of liquids. If a very narrow glass tube were used, and it was filled up to a certain level, with one liquid, say at 15° , then put into a cylinder filled with water and this heated to a higher temperature, a different volume would be found; and by the two readings it might be possible to determine the rate of expansion of the two liquids. He had done it at various temperatures with different liquids, such as sulphuric acid, nitric acid, muriatic acid, and nitro-glycerin. He had

found that the tables and formulae he had consulted in that connexion did not agree with his observations, and he could not find the proper ratio. Even taking the expansion of water as a standard, and calculating by the usual formulae he could never get a proper result. He had tried to take into account a factor for the expansion of the glass, but he was bound to say that he had never arrived at satisfactory results, and he would be very glad to see the question taken up by someone competent to deal with it.

Mr. CLAYTON BEADLE thought that Dr. Wright had demonstrated that the difference in the expansion of liquids was to be accounted for by the fact that they had been formed at varying temperatures. It seemed to him that they could not be read at one and the same temperature, unless it was known that the coefficients of the expansion of the fluids and water were the same. If a fluid was taken at 100°C . and compared with water at 100°C ., the specific gravity could not be the same as if determinations were made at 0°C ., unless it were certain that the coefficients of expansion in the waters were identical.

Dr. SAMUEL RIDEAL thought that Dr. Wright's suggestion with reference to the outer cylinder was a very good one; but that it would not be applicable in the case of dark liquids.

Mr. ARNOLD PHILIP thought that Mr. Guttman's question and his own were very much the same, namely, how to distinguish the difference between the expansion of a solid substance like glass, and the expansion of such a substance in the form of a tube or a hydrometer float.

Dr. WRIGHT, in reply, said that as regarded the remarks that had fallen from Mr. David Howard, he cordially agreed with that gentleman, and thanked him for his corroboration of some points, especially the extreme desirability of not trusting implicitly to instrument makers, who were not infallible; even with the best it was necessary (just as in the case of a variety of other political and social matters) to look carefully after and verify the products of their industry, which were, in many respects, wonderfully delicate. He would not like to say a word against the skill of instrument makers, after having obtained from them such excellent instruments as he had exhibited to the meeting that evening. But when an extremely high degree of accuracy was required, unless the instruments used had been carefully checked, no one was warranted in placing implicit confidence in the numerical results obtained. Even with such an instrument as a chemical balance, it was absolutely imperative that each weight should be checked against the others, so that the relative values of all the weights should be exactly known. Unless that were done, the results would always be affected by a certain amount of inaccuracy, due to imperfect adjustment of the weights. One or two speakers had referred to the expansion of glass, questioning whether the same rate of expansion would apply to a solid block of glass as to a hollow vessel. He did not see why it should not. A tube might be regarded as a solid block of glass, from which the inside of the block had been removed; then, what would apply to the outside would equally apply to the inside; and any argument which applied to the outermost layer, would also apply to the innermost layer. For the present purpose, they might be satisfied with the fact that all physical inquirers who had used glass instruments for such matters as the determination of the rate of expansion of mercury, and such like intricate physical problems, had satisfied themselves that within the limit of observation the principle was true, that the capacity of a hollow glass vessel increased by an increment of temperature at the same rate as the bulk of a solid block of the same material. He thought that if that was stated as a warrantable deduction in the present state of knowledge, it perhaps met the difficulties that seemed to have occurred to the gentlemen referred to. Regarding Mr. Guttman's difficulty with reference to the determination of specific gravity, that the value found at one temperature is not the same as that obtained at another temperature, that must necessarily be the case, unless the standard fluid and the substance compared with it expanded at

exactly the same rate. If an inexpandible fluid were compared with water at 100° C., its specific gravity at that temperature would be something like 4 per cent. higher than the value obtained at 15° C.; whilst if the fluid were more expandible than water, its specific gravity would be less at the higher temperature, and *vice versa*; so that, in the one case, the specific gravity would be greater, and in the other case, less at 100° C. than at 15° C. It was to points of that kind that he had wished more particularly to refer in his opening remarks in pointing out that current technical literature was attended with a considerable degree of uncertainty as regards the exact meaning of certain numerical quantities, through the improper use of terms and the incorrect application of them in defining quantities of this description. He did not like to appear invidious, but might mention as an example that one very well-known author had spoken of the ratio of the weight of a given volume of melted fat at 100° F. to the weight of the same volume of water at the same temperature as being the "actual density," a wholly improper expression; for the term density involved a conception of something more than a simple numerical ratio; it involved the fundamental notions of mass and volume, and the use of a phrase of that kind implied a considerable confusion of ideas; apart from which the "actual density" at 100° F. as thus defined was a value which was absolutely identical with the "specific gravity at 100° F.," and was, therefore, a needless expression, even if correct. Two speakers had referred to the possibility of error on account of the sticking of the hydrometer against the side of the vessel; and another possibility of error through the formation of bubbles upon the instrument. The former difficulty was less likely to occur with hydrometers of cylindrical belly, floating perfectly upright in a smooth surfaced jar; the latter source of error was a very considerable difficulty in all cases, but it applied equally to all forms of instrument with which he was acquainted. The two fluids (diluted spirits of wine, and sulphuric acid) on the table had not liberated any bubbles during their use as examples, but it was quite possible that others might have done so. As regarded the bobbing up and down of the hydrometer, there was a very simple way of getting over the error that might occur through the adherence of a film of liquid to the upper part of the stem; and that was, simply to lift it up about an inch or so, carefully wipe the stem, and gently let it go so that it would quietly subside. Mr. Fulton had referred to an instrument (see below) which he (Dr. Wright) had not had the pleasure of being able to examine thoroughly; and he confessed that he did not quite understand its *modus operandi*; but it appeared to him that the part which corresponded to the shank of a hydrometer was somewhat wide; and, therefore, it could hardly be expected to compare in delicacy with the instruments he had exhibited. The instruments he had on the table had equivalent lengths of 750 to 1,250 millimetres equal to some 30 to 50 inches, so that each millimetre of stem represented about $\frac{1}{750}$ to $\frac{1}{1250}$ of the whole instrument; i.e., for an instrument standardised with water a difference in specific gravity of 0.0001 represented about one-tenth of a millimetre. But in the instrument brought before the meeting by that gentleman, it appeared to him (Dr. Wright) that the graduated tube was very much wider, so as to seriously impair the sharpness of its reading. He spoke under correction, as he had not had an opportunity of closely inspecting the apparatus; but that was the objection which occurred to him at the first blush. A speaker had referred to the expansion of the liquid, and had asked whether the indications of a "millimetre areometer" would be exact at a temperature higher than that at which it was standardised. Certainly not, unless it was known what was the rate of expansion of the substance dealt with relatively to water so as to make the necessary correction. If a given instrument were calibrated and set for a particular temperature, say 15° C., it could be used at that temperature with a fair degree of accuracy; but if it were required to work at a widely different temperature, say 100° C., it should be calibrated at that temperature also. The same principles applied as in the case of a pycnometer; so far as the effect of expansion was concerned, that could be calculated in

much the same way as that described for pycnometers in the paper; but there was another point to consider, viz., that if the temperature of the jar varied, the length of the millimetre scale etched thereon also varied, so as to represent a lesser length than 100 millimetres at a temperature below the normal one for the instrument, and *vice versa*, involving an additional correction. Dr. Rideal's experience with the Westphal instrument seemed to have been more unfortunate than his (Dr. Wright's) and worse than that of most others who had used it. The results which he (Dr. Wright) had obtained with it and similar instruments, had led him to believe that, except in determinations involving accuracy to more than three places of figures, it was sufficiently accurate to be of considerable practical use. One speaker had stated his opinion that the use of an arrangement of the kind described by him would be limited to fluids not deeply coloured. It was perfectly true that in the case of a dark fluid it was difficult to read the meniscus, but in that case the level of the top of the liquid could be easily read; whilst with a properly proportioned jar, not too wide, the etched rim could also be easily read, there being only a thin column of fluid round the bulb of the instrument.

SPECIFIC GRAVITY APPARATUS.

BY H. B. FULTON, F.C.S.

It seemed to me that while the little piece of apparatus which I have now the pleasure of exhibiting is perhaps scarcely important enough in itself to merit an independent communication to the Society, it might, in connection with Dr. Wright's paper "On Specific Gravities for Practical Purposes," be not altogether devoid of interest.

In bringing this before the Society, I make no claim of originality, having seen the principle applied some years ago in America, where a common test tube was employed for the purpose. I have, however, suggested the addition thereto of a bulb for mercury or shot to weight the tube as in the case of an ordinary hydrometer.

The apparatus consists of a glass tube, having as uniform a diameter as possible, graduated from zero upwards—a scale of millimetres being a convenient one—and weighted with mercury so as to maintain a vertical position when floated in water. The neck by which the mercury bulb is attached is comparatively a long one, so that the centre of gravity may be as low as possible. The lower part of the tube may with advantage be blown so as to have a small flattened protruding bulb to act as a fender (Fig. 1), and thus insure more accurate readings by preventing the tube from clinging to the sides of the test jar; or the same result may be accomplished by other means.

The *modus operandi* is as follows:—

Water is first poured into the tube to fill it at least to zero on the scale. A little more does not matter, and there must be sufficient to cover completely the specimen whose specific gravity is about to be taken. Suppose it to have been filled exactly to zero, the tube is now floated in a jar of water, and the level at which it floats is read off. This may be, say 20 (as at Fig. 2). The specimen, perhaps a piece of galena, either as a lump or in powder, is now dropped carefully into the tube, which at once sinks, say to 55 (as at Fig. 3), and the weight of the specimen is thus ascertained as 55—20 = 35.

At the same time, however, the volume is obtained by noting the displacement of the water *inside* the tube; and again assuming this reading to be 5, we have at once

$$\text{sp. gr.} = \frac{35}{5} = 7.$$

Although, obviously, determinations cannot thus be made with the same accuracy as with the balance, yet the apparatus admits of the specific gravity of vesicular bodies, such as slags, being taken rapidly and easily in the state of grains or powder, with sufficient exactness for most practical purposes. By diminishing the diameter of the tube, greater

delicacy can of course be attained, and I suggested to Messrs. Townson and Mercer, who made the tube now before you, that they should prepare tubes for sale, of three different diameters, perhaps 10 mm., 18 mm., and 25 mm.

FULTON'S SPECIFIC GRAVITY TUBE.

STUDIES ON ARTIFICIAL MUSK.

ALBERT BAUR, PH.D.

SOME years ago, together with W. Kelbe, I isolated from rosin spirit (Harzessenz), a butyltoluene, which proved to be a meta-derivative. (Ber. 16, 2559.)

According to my more recent investigations on this subject I have succeeded in proving that by the action of nitric and sulphuric acids on this hydrocarbon, a crystallisable compound is formed which possesses in a very marked degree the odour of musk. The production of this artificial musk is now patented in all countries. The preparation is known in commerce under the name "Musk Baur." (This Journal, 1889, 1004.)

In the Compt. Rend. 1890, 111, 238, and also Chem. Zeit. 1890, [67] (this Journal, 1890, 964), there is a notice published by me showing that artificial musk is a trinitro-derivative of butyltoluene of the formula $C_6H_4(CH_3)(C_4H_9)(NO_2)_3$. I have extended this investigation, and now beg to communicate the further results obtained, (this Journal, 1891, 1024).

The hydrocarbon of rosin spirit, like the compound synthesised from tertiary butylchloride and toluene, both of which yield artificial musk, are shown to be one and the same thing, viz., tertiary butyltoluene.

Mononitrobutyltoluene $C_6H_4(CH_3)(NO_2)C(C_4H_9)_3$. When fuming nitric acid is slowly added to the solution of the hydrocarbon in glacial acetic acid, an oil is obtained which refuses to solidify even in a freezing mixture, and can be volatilised with steam. On distillation under the atmospheric pressure it decomposes, but *in vacuo* it distils without decomposition at 160° – 162° . It is a yellowish oil

of peculiar odour, not pleasant, and unlike that of musk. On long standing in the air it becomes brown.

By the action of excess of nitric acid this mononitro-compound is converted into the trinitro-compound ("artificial musk").

By warming the oil for some time on the water-bath and precipitating with water, a solid product was obtained smelling of musk, and crystallising from alcohol in yellowish white needles, melting at 96° – 97° .

Dinitrobutyltoluene, $C_6H_4(CH_3)(NO_2)_2C(C_4H_9)_3$

When the hydrocarbon is allowed to drop into fuming nitric acid of sp. gr. 1.5, the liquid being strongly refrigerated, and the mixture afterwards let stand at the ordinary temperature, a mixture of mononitro-, di-, and trinitro derivatives is obtained. On distillation with steam the mononitro product first passes over, and then follows a mixture of mono- and dinitro-compound. The trinitro-derivative remains behind on steam distilling, and contains a small quantity of dinitrobutyltoluene.

On allowing the original product to stand for some time at rest, the trinitro-derivative for the most part crystallises out.

To obtain the dinitro-compound from the residual oil, the latter is submitted to distillation *in vacuo* repeatedly. The fraction received over at 224° – 225° is pure dinitrobutyltoluene. It is a brown oil of very unpleasant odour, not solidifying in a freezing mixture. When this oil is treated with excess of the sulphuric nitric acid mixture, trinitrobutyltoluene results.

Trinitrobutyltoluene (Artificial Musk)—

The simplest method of preparation is from the hydrocarbon direct. By allowing the hydrocarbon, butyltoluene, slowly to drop into 5 times its weight of a mixture of 1 part of nitric acid of 1.5 sp. gr., and 2 parts of fuming sulphuric acid of 15 per cent. of anhydride and warming the mixture on the water-bath for about 8–9 hours. On pouring into water a crystalline mass is precipitated, consisting of trinitrobutyltoluene, but not quite pure. To obtain a perfectly pure article, capable of giving good analytical figures, it is necessary to nitrate the product once more. By crystallising the product from alcohol, yellowish-white needles melting at 96° – 97° are obtained, and these have an intense odour of musk. The compound is insoluble in water, but easily soluble in alcohol, ether, petroleum spirit, benzene, and chloroform. It is only very slightly volatile on attempted steam distillation. By dissolving equal molecular weights of trinitrobutyltoluene and naphthalene in boiling alcohol and heating the solution for some time under inverted condenser, on cooling large yellow plates are obtained, melting at 89° – 90° .

With regard to the constitution of the trinitrobutyltoluene there are four formulae possible—

The three first have the common peculiarity that in each case one nitro-group exists in the ortho position to another nitro-group, whilst in the fourth formula all three nitro-groups are respectively in the meta position to each other. Now, the investigations of Laubenheimer, Hepp, &c. have shown that the compounds in which the nitro-groups stand to each other in the ortho position, very easily exchange one of these nitro groups for an OH, NH_2 , or NHC_6H_5 group when treated with alkalis, ammonia, or aniline

respectively. In the first two cases the nitro-group is eliminated as nitrite, in the third case it converts the aniline into diazoamidobenzene, $C_6H_5 \cdot N : N \cdot NC_6H_5$. If the nitro-groups are not in the ortho position, then alkalis and ammonia are without action, and aniline gives rise to addition products. No alteration with alkalis and ammonia taking place, and an addition compound with aniline without any formation of diazoamidobenzene being obtained, the fourth formula is confirmed as the true one.

Homologues and Isomerides of Artificial Musk.—A series of these has been very carefully prepared and qualitatively tested. Very many of them possess the smell of musk, but as far as regards technical value they are all inferior to the trinitrobutyltoluene. For example, the trinitro-compound of butylmethylxylene has been prepared. It possesses a strong odour of musk, and has the formula—

By-products formed in the Preparation of Butyltoluene.—Butyltoluene is by no means the only product of the action of butylbromide upon toluene in presence of aluminium chloride. To purify the substance, it is necessary to subject the product of the reaction to repeated fractionation. Even by the use of perfectly pure toluene and pure isobutylbromide, besides butyltoluene, also butylbenzene, butylxylene, butylethylbenzene with dibutylbenzene, dibutyltoluene, and other products as yet undistinguishable, are obtained.

The formation of butylbenzene, xylene, and ethylbenzene is explained by the fact that in the reaction of Friedel and Crafts (Compt. Rend. 101, 1218) toluene splits up under the influence of aluminium chloride partially into benzene on the one hand, and xylene and ethylbenzene on the other, and these naturally become butylated, like the toluene itself.

Among the products distilling between 170° and 200°, which I have specified in my patent as applicable for nitration, all these compounds are contained, and the corresponding trinitro-derivatives find their way into the crude artificial musk. Later on, it was however found best, even for technical purposes, to subject the butyltoluene to a complete purification to begin with.

When the bromide is employed, which has been prepared from the ordinary commercial butyl alcohol and which always contains amyl alcohol, the crude hydrocarbon mixture, as per patent, boiling at 170°–200°, contains besides butyl derivatives, also the corresponding amyl derivatives. These also on nitration yield substances smelling of musk, but of a coarser description of odour, and which are much more difficult to crystallise. For technical purposes, then, pure butyl bromide must be employed.

Anisol and Cresol Derivatives, and another Form of Musk.—On account of the analogies of the phenol ethers with the hydrocarbons, it seemed to me of interest to include them in the scope of my investigations. I have, to begin with, introduced the butyl group into anisol, $C_6H_5 \cdot OCH_3$, by means of the Friedel and Crafts' reaction, and then subjected the butylanisol—

thus obtained, to nitration. The Di- and Trinitrobutylanisol are crystalline bodies possessing no smell of musk.

The Trinitro-derivatives of the butylated *p*-cresol- and *o*-cresol-ethers have, according to my researches, the following constitution—

They exhibit no odoriferous properties worthy of notice or remark.

The butyl-group in these ethers is of course also the tertiary.

The trinitro-derivative of the butylated *o*-cresol ether is a beautifully crystalline product. It forms shining yellowish-white needles melting at 69°–70°. This ether was also obtained from the *m*-butyltoluene sodium sulphate by fusion with potash, and by nitration and subsequent etherification of the phenol thus obtained (Ber. 16, 2561).

The trinitro-derivative of the butylated *p*-cresol ether, on the other hand, is obtained in the crystalline form with very great difficulty. When, however, pure *m*-cresol ether is boiled with isobutyl bromide or pseudobutyl chloride and aluminium chloride, a butylated *m*-cresol ether is obtained, boiling at 222°–224°, and which on treatment with the nitro-sulphuric acid mixture yields a trinitro-derivative of intense musk-like odour. This compound possesses the formula—

This ether crystallises from alcohol in beautiful yellowish-white plates. A British patent has been recently granted for the preparation of this musk-like cresol ether.

If meta-cresol be treated with butyl alcohol and then with chloride of zinc, and the mixture boiled under the inverted condenser, an unsymmetrical butyl-cresol is obtained, which when etherified and nitrated, yields a product possessing an odour closely resembling the so-called civet ("civet").

DISCUSSION.

The paper having been read by Mr. WATSON SMITH.

Dr. ALDER WRIGHT wished to ask him whether the author had examined the nature of the products obtained by the methods patented by Valentiner (Eng. Pat. 15,687 of 1890; this Journal, 1891, 571), where certain benzene hydrocarbons, oil of turpentine, &c., were treated with butyl or other homologous alcohols in presence of sulphuric acid, whereby condensation was brought about, producing hydrocarbons and sulphonic acids thence derived, the former of which gave an insoluble musk on nitration, and the latter a soluble musk. It would thence seem as if a variety of homologous nitro-derivatives existed, all more or less possessing the odour of musk. Were any particular members of this group better suited than others for technical purposes? and if so, which?

Mr. PETER MACLEW said there was no doubt that the subject before the meeting, from a commercial point of view, was of immense interest; but in his opinion it was of equal interest that the meeting should know that artificial musks, from the point of view of the consumer, had not been quite the success which had been anticipated. This fact was probably due to the assumption that musk was used *per se* as a perfume. It was not so; the principal use of musk being to develop, fix, or "round off" the odours of other perfumes. This property did not appear to be possessed by the artificial musks. There was another fact in regard to artificial musk which he had noted on its introduction, and that was, that it underwent some modification in presence of acids, which fact had a very material influence upon the use of such substances in confectionery, in which trade there was undoubtedly very large quantities of musk employed, as was also the case in tobacco manufacture. It would be of immense advantage to those industries in which musk was used if Dr. Baur would extend his studies to the investigation of the reactions or decompositions between artificial musk and those bodies with which it was likely to come in contact. It was necessary that they should have knowledge on this point before they could say whether artificial could take the place of natural musk. The supply of the latter could not last for ever, and although the extermination of the musk deer

might not be a question for the present generation, it certainly would be for the next, or the following one; and what there would be to fall back upon then it was difficult to conjecture, unless a satisfactory artificial article could be produced.

Mr. A. G. GREEN inquired whether it had not been shown in a recent number of the *Berichte* of the German Chemical Society, that the soluble musk obtained according to Valentiner and Schwarz's patent, owed its smell to a small quantity of trinitrobutyltoluene with which the commercial product was contaminated, and that the pure sulphonate was odourless. The fact that the trinitrobutyltoluene was insoluble in water would not disprove its presence, as it might be dissolved in small quantity by the sulphonate; *a priori*, it was difficult to conceive of the sodium salt of a sulphonic acid having an odour, on account of the extreme non-volatility of such bodies.

Mr. WATSON SMITH, in reply, said that Dr. Baur had already investigated the homologues of the butyltoluene musk, and he had stated definitely that none of them possessed an odour comparable with that of his pure trinitro-product for fineness and purity. With regard to the question of the blending capacity of the artificial musk, he, Mr. Watson Smith, had found on reference to Piesse's work on perfumes, that it had not that property in the same degree as natural musk. What he understood by this was that whilst natural musk had an extraordinary power of blending its perfume with other odours to agreeable results, the artificial product lacked this capacity. Natural musk resin had an entirely different composition. With reference to soap manufacture, in connexion with the question of any superiority or inferiority of the water-soluble sulphonated musks for scenting purposes, it appeared to him to be a question of how much of such soluble products were required to scent one ton of soap as compared with the musk of M. Baur. Manufacturing practice would soon settle this point. Otherwise he was perfectly at one with the opinion of Mr. A. G. Green.

Mr. MACEWAN remarked that the artificial article made from oil of amber was used in the manufacture of certain soaps, in which natural musk could not possibly be used owing to its high price.

Mr. WATSON SMITH, continuing his reply, said that it was a current opinion that the most valuable application of artificial musk would be in the scenting of soaps.

Dr. A. BAUR replied to the following effect by letter:—Not only he, but also Professors Graebe, Noeling, Nietzki, and Witt had repeated the process described in the specification No. 19,687 of October 3rd, 1890, of Valentiner. By the reactions which take place when concentrated sulphuric acid acts upon butyl alcohol and oil of turpentine, small quantities of butylated aromatic hydrocarbons are formed, which are volatile with steam, and on nitration yield impure and ill-flavoured musks. The larger portion of the product is non-volatile with steam, and furnishes on nitration no musk at all. As regards the reaction with the butyl alcohol and sulphuric acid, on the one hand butylxylene is formed, which on nitration yield Baur's trinitro-derivative, whilst on the other, butylxylene sulphonic acid—

is produced. Now on nitration of this latter compound, trinitrobutylxylene sulphonic acid is produced which is, as Mr. A. G. Green suspected, without odour; and on continued nitration, suffers decomposition with loss of the sulphy group and formation of trinitrobutylxylene. A complete report on this subject is given by Noeling in the *Berichte*, 1892, 789, where he states:—"The so-called Soluble Musk of Valentiner owes its odour to small quantities of trinitrobutylxylene." Trinitrobutylxylene, although insoluble in water, dissolves to some extent in the solution of the nitrated sulphonic acid and its salts. A really soluble artificial musk does not exist. He (Dr. Baur) had heard from various perfumery experts and firms that the artificial musk had proved itself extremely well adapted for mixing

with other perfumes, and that, like natural musk, it possessed the power of fixing the latter as well as amalgamating with them.

Whilst he was working out his process, it subsequently appeared that two other German chemists, Messrs. Sehmanfer and Hupfeld, had been working on the same lines. Whilst later, as to date of application in Germany, these chemists were first in England, viz., Eng. Pat. 18,521, December 18, 1888, whilst his patent, No. 4963, was dated March 21, 1889. This matter was now fully settled, both patents being in the hands of the same firm, the *Fabriques de produits chimiques de Thann et de Mulhouse*, and the further scientific investigation of the subject now rested solely with himself.

NOTES ON ROSIN OIL.

BY F. H. LEEDS, F.I.C., F.C.S.

CHENEVIER (*Monit. Scient.* 1890, 4, 685–689; this *Journal*, 1890, 825) has stated that rosin oil "of the first distillation" may be distinguished from that of the second by the amount of free acid present, and gives as the limits of the acidity from 4 to 10 per cent., the molecular weight of the acids being assumed to be 302.

Rosin oil "of the first distillation," *i.e.*, an oil which has been distilled once, the spirit it contains being subsequently removed either by steam or fire heat, varies considerably in its composition, according to the design of the stills, and the consequent greater or less ease with which the rosin can volatilise unchanged during the distillation; the acidity of commercial samples varying from about 15 to 24 per cent. These crude oils usually have a blue fluorescence, but by heating to a temperature of 150° C. for 3–4 hours, to remove the last traces of spirit, they lose from 1 to 5 per cent. by weight, and the fluorescence becomes green. Oils containing a higher percentage of non-acid substances are also met with, and with little trouble may be prepared, having only about 0.4 per cent. of acids.

The figures for acidity given above are obtained by titration of the alcoholic* solution of the oil with caustic potash and phenolphthalein; their molecular weight being taken at the figure given by Chenevier (*cf. ante*). By boiling the oils with excess of alcoholic potash and titrating back with acid, another—higher—figure is obtained, the difference between the two varying from 1 to 9 per cent., but having, as reference to Table I. will show, apparently no connexion with the degree of purity of the oil.

TABLE I.

Sample.	Acid by Titration.	Acid by Saponification.	Difference Per Cent.
A	22.71	31.07	8.36
B	14.51	22.20	7.68
C	0.45	9.72	9.27
D	13.11	14.52	1.41
E	0.36	1.84	1.48

Of these samples E was a laboratory oil, prepared in glass, and D was a mixture of about equal parts of A and B, prepared for a special purpose.

The first three samples were exposed in evaporating basins to the air of the laboratory for five months from April to September, to see the effect of partial drying. At the end of the time they were found not to have increased notably in viscosity, but A was dry at the edges; they were then well mixed up by the aid of heat and

* In the case of the crude oils, solution is much aided by the addition of a few drops of toluene.

thorough stirring and again titrated; the results being shown in Table II.:

TABLE II.

Sample.	Acid by Titration.	Acid by Saponification.	Difference Per Cent.
A	23.28	24.90	1.62
B	11.48	16.09	1.59
C	9.55	12.21	3.66

It is to be noticed that the figures in the first column show hardly any change—the decrease in B being probably an experimental error. Some of the A oil after exposure was poured on to glass plates and again exposed till dry to the touch; the film was then scraped off the glass, and gave, on analysis:—by titration, 24.60 per cent., by saponification, 37.00 of acids.

By boiling with alcoholic potash and treating as described in Allen's Commercial Organic Analysis for the estimation of saponifiable matter, figures agreeing well with those obtained volumetrically could not be obtained; sample B giving gravimetrically 16.12 per cent. of acids instead of 14.52: further experiments, which are still in progress, showing that the molecular weight of the resins is higher than 302 (Chenevier, *loc. cit.*). The author hopes to give further results in a future communication.

The following have been elected to fill the vacancies, and will take office in July next:—*Vice-Chairman*: E. Carey. *Committee*: J. Campbell Brown, Jos. C. Gamble, G. Schack-Sommer, and A. Norman Tate.

Meeting held Wednesday, April 6th, 1892.

MR. A. NORMAN TATE IN THE CHAIR.

ADJOURNED DISCUSSION ON MR. A. E. FLETCHER'S PAPER ON MODERN LEGISLATION IN RESTRAINT OF THE EMISSION OF NOXIOUS GASES FROM MANUFACTURING OPERATIONS. (See Vol. XI., page 120.)

MR. EUSTACE CAREY opened the discussion, and said—

I purpose this evening to make some remarks, which shall be few and brief, by way of introducing a discussion upon the subject of Mr. Fletcher's interesting paper of January last, with the intention of proposing a resolution and

of obtaining the views of this Section as to what, if any, amendment of the Alkali Works Regulation Act should be recommended in the interest of the public, amendments which shall be at the same time without injury to the manufacturer.

In making the following remarks I wish it to be understood that I am giving only my own individual opinion, I do not pretend to represent any particular manufacture, and though, of course, I can only speak from my experience as an alkali manufacturer, I shall endeavour without fear or favour to speak in the interest of chemical industry generally, and I hope with a due regard to the interest of the public of which we form a part.

So far the alkali manufacturer has been in the eyes of the public and of the Legislature the first and chief object of attention, though it has all along been obvious and admitted that there are other industries which have hitherto received no attention whatever which deal with and of necessity evolve into the atmosphere the very same gases as those produced in the manufacture of alkali. The Act of 1863 was directed against alkali works alone, and though the subsequent Acts have been concerned with some other industries their chief object has been the regulation of alkali works.

One reason for this is readily seen, viz., that in alkali works the gases are evolved in such a manner that they can be regulated and their escape controlled with comparative ease. Another reason is that the foremost alkali makers, when legislation was first proposed, happened to be men of singularly open mind, public spirited, and sagacious (as many of these men have passed away, I trust that I may be permitted this tribute to their memory). They began by frankly admitting the fact that the gases evolved from their works had done harm to vegetation, that within reasonable limits the escapes of these gases might be controlled, and they expressed themselves willing to incur reasonable expense in erecting plant for the more perfect condensation of such gases. They went further; they cordially assisted the Government in framing a working Act, and when that Act was passed they treated the inspectors, who had been appointed, in a thoroughly friendly way, and gave them, so far as I know, every assistance in their power. They were sagacious enough to see two things; one was that a reasonable regulation of escapes would be ultimately in favour of the manufacturer who was possessed of capital and skill; secondly, that the fact of their works being so conducted as to meet the requirements of the inspectors would tend, and rightly tend, to protect them from vexatious actions for damage. These views and their action have been justified by the event, for, the Acts being framed in a reasonable manner, manufacturers generally have found no great difficulty in complying with the regulations, escapes have been greatly lessened, vegetation in the neighbourhood of alkali works suffers less than it did 20 or 30 years ago, notwithstanding the fact that alkali works have largely increased during that period, the public have been protected and the manufacturer, to say the least, has not suffered.

So much for the past; let me, with equal brevity, now speak of the future.

Firstly, then, with regard to Mr. Fletcher's suggestion, that works should be no longer scheduled but that gases should; that is to say, instead of naming a list of the works that are to be inspected and the operations of which are to be controlled as to their means of preventing escapes, a list of gases should be named, and that all works that are liable to evolve these gases should be brought under inspection and eventually under reasonable regulations with a view to the prevention of escapes. With this suggestion I quite agree, the present system of naming certain works and only certain works results in glaring anomalies and affords another instance of the old saying that "while one man may steal a sheep another may not look over a hedge." Under the present system *ex. gr.*, as has been often pointed out before, the alkali maker in the manufacture of sulphate of soda is tied down by stringent regulations; he must catch and condense all or nearly all his HCl, he must catch and condense all or nearly all his chamber SO₂ and SO₃; but the glass manufacturer on the other hand buys sulphate of soda and in many cases common salt and calmly decomposes those

substances with SiO_2 and makes no attempt to catch and condense either his SO_2 or HCl . The whole of these gases escape into the atmosphere, and as the alkali manufacturer and the glass manufacturer are often next-door neighbours the unfortunate alkali maker is frequently held responsible for annoyance and damage to which perhaps he does not contribute more than one hundredth part. The same observations hold good in respect to copper smelting; the smelter by the dry process is under no inspection and under no obligation to even try to condense his SO_2 , while the wet process metal extracting works are defined to be alkali works and therefore under regulations as stringent as those of ordinary alkali works.

Of course it will be argued that in the case of glass works and dry process copper works, there is no means—no practicable means—of condensing these gases. That may be very true at present and no person outside a lunatic asylum would dream of placing the same restrictions upon them as upon alkali works; but there is no reason why no attempt should be made to grapple with the difficulty, but rather more reason for putting judicious but not vexatious pressure upon such manufacturers to try to make them improve their processes and appliances in the interest of the public. I think also, that it will be better to name certain gases than to take a wider definition—the gases when enumerated are something upon which the inspectors can definitely act. If a wider definition is attempted such as that proposed by Dr. Brown, viz., “any gas injurious to health or property,” the inspectors would have an almost insuperable practical difficulty before them: they or the Government for them, would have to decide from time to time, amidst conflicting testimony, what gas is, and what gas is not harmful, and then having decided that they would have to say what percentage of such gas is harmful. Is 0·2 per cent. of CO , prejudicial to health or 0·4 per cent.? Is 0·01 gr. of HCl or 0·001 of Cl in a cubic foot of the air of a neighbourhood prejudicial or otherwise? Now these questions would lead to endless delay in the practical working of any Act, and I submit that our Act should be so amended as to enumerate gases which are admitted to be harmful, which are known to be manufactured and which are liable to escape in sufficient quantity to be a serious annoyance to the public.

I would suggest that the Act be so drafted that the list of these gases can be amended by provisional order or otherwise if and when in the opinion of the central authority necessity arises.

The Act should provide that any works where these gases are manufactured shall be inspected by qualified inspectors appointed by the central authority, that when such works are under inspection it shall be competent for the central authority from time to time to define within what limits, if limits are practicable, escapes may be tolerated; in other words, a “best practicable means clause” of elastic construction should be provided.

By such a clause I do not mean that inspectors should have the power of saying to a manufacturer “You must use such and such means, you must use this or that apparatus or invention for the purpose.” Such power is obviously open to great abuse, but the inspector should have power when authorised by the central authority to say to a manufacturer, “It has been proved practicable to reduce these escapes to such and such a limit, you must now reduce them to this limit; adopt what means you please, put up what form of plant you like, only reduce your escapes to what is now known to be reasonably practicable. You shall have three months, six months, or whatever time is necessary to effect your alterations, but by such and such a date your escapes must be reduced to the required point, otherwise I shall be compelled to take action against you.”

The “best practicable means” should be therefore understood to be any means which will attain that result which is considered by the central authority to be the best practicable result for the time being.

Now it may be argued by those who do not wish to see any extension of legislation, that “British manufactures must not be handicapped by regulations which are not in force in foreign countries, for if they are so handicapped the foreign manufacturer will have an unfair advantage over us.”

I reply, if the proposed regulations are such that the British manufacturer is really at a disadvantage thereby, such regulations are not reasonable because they are not politic, and being unreasonable and impolitic they are not likely to be suggested by any responsible authority.

This part of the question appears to me to resolve itself into this: Can we trust the Government?

I venture to say we can, for I believe that no Government, be it Conservative or Radical, will ever have the desire, or even if it had the desire will ever be allowed, to hamper our manufacturers with unreasonable and impolitic restrictions.

I think that the experience of the last 30 years shows us that in noxious vapours legislation we have been careful of the manufacturer; it has been cautiously tentative, and, if you please, illogical; Englishmen often appear illogical; all practical men do.

Suppose for a moment that we had been what some persons may call strictly logical and had insisted upon having no anomalies, we should have been forced into one of two courses: on the one hand, we might have said, for example, all works that evolve sulphuric acid and hydrochloric acid must condense, therefore glass works shall do so as well as alkali works; or, on the other hand, we might have said because glass works cannot control their escapes therefore we won't ask alkali works to control theirs. The former alternative if vigorously carried out, would have injured or might have ruined the glass trade, the latter would have indefinitely delayed improvement in the alkali trade. No, thank goodness, we have not been “logical”; we have been practical and have done the easy work first; if we had not so acted we should possibly never have done any work of the kind at all, and in any case it would have been much delayed.

I submit the time has come when by the experience we have gained in doing the comparatively easy task of regulating alkali and some other manufactures, we should put our shoulders to the wheel again and see if we cannot take another step forward, and that next step seems to me to be the amendment of the present Act in the direction of scheduling certain gases and not certain works, and in the inspection of all works that deal with those gases.

This Government is preparing to amend the present Act, and will, we are informed, bring in a Bill this session with that object.* It is, I think, for this Society, the great representative society of the chemical manufacturers of the United Kingdom, to watch and to influence legislation in the interest, firstly, of chemical industry, but not forgetting that chemical industry has its duties as well as its rights. I have no doubt that the Parliamentary Committee of the Council are fully alive to this. But as the new Bill affects primarily a branch of our trade, the largest centre of which is in the neighbourhood of Liverpool, it seems highly desirable that this Section, having special knowledge of that part of the subject, should take action and confer with the Parliamentary Committee. I have, therefore, much pleasure in proposing the resolution, which reads as follows:—

“That a Committee (with power to add to their number) be appointed by this Section to confer with the Parliamentary Committee of the Council of the Society, to consider how the Alkali Works Regulation Act may be amended in the interest of the public and without injury to the manufacturer.”

Mr. J. C. GAMBLE, in seconding the resolution, said he quite agreed with Mr. Carey that gases should be scheduled and not processes. At the same time he had not such great faith in the Local Government Board as to at once leave it to them to say in all cases what were the best practicable means. He would prefer in the case of processes widely differing from those that have already been under inspection that at first they should simply be put under inspection, and when the inspectors had had sufficient time to become thoroughly acquainted with all the conditions under which they were carried out, they might then be put under the “best practicable means” clause.

* A Bill has since been brought in and was read for the first time in the House of Commons on Friday, April 8, 1892, and will be found printed *in extenso* on p. 382 of this issue.

Dr. HURTER, in supporting the resolution, drew attention to the Act as foreshadowed in Mr. Fletcher's paper.

He was sorry to find that the numerical standard limits of escape provided by the Alkali Acts of 1863, 1874, and 1881, were to be abandoned, and that the "best practicable means" clause was to take their place entirely. From Mr. Fletcher's paper he gathered that the new Act would read as follows: Noxious Gases Act: Every manufacturer must use what in the opinion of a judge and jury were the best practicable means of preventing the discharge into the atmosphere of any such gases evolved in his works, of which 10 neighbouring householders made *bona fide* complaints. If the Local Government Board were satisfied that the complaints were *bona fide*, their inspector would institute proceedings against the manufacturer. Such an Act would not work. A judge and jury would be the authorities who decide whether the best practicable means had been used. The noses of 10 neighbouring householders would take the place of anemometers, aspirators, &c., and it might well be asked, "Who is my neighbour?" Mr. Fletcher had no doubt the best intentions, and thought that such an Act was simple and not indefinite, but he (Dr. Hurter) was afraid that to the counsel of a defendant company, the Act might not read quite so definitely, and provided the means whereby any farmer or householder might harass the manufacturers.

He approved of the suggestion to schedule the gases rather than the works, but pointed out that the numerical standard limits of escape should be retained. These could not of course be applied at once to all the works. Escapes of sulphurous acid from glass and copper works were most difficult to deal with, and the question arose, supposing they succeeded in suppressing all the gases evolved in chemical works, would they derive any great benefit from it as regards the purity of the atmosphere? It was admitted on all sides that the largest pollution of the atmosphere was due to the combustion of fuel, the sulphur of which was by far the greatest source of sulphurous acid. He did not think that the loss which might be inflicted by unduly harassing the manufacturers would be compensated by the increase in agricultural profits, and he thought that while they were obliged to control the escape of these gases to such an extent that they would not be injurious to health, they must stop at that limit and not press for more than would insure that, considering that our population lived chiefly on other than agricultural pursuits.

Mr. TERRY did not approve of the proposal to schedule the gases. He thought it would cause serious inconvenience to many industries where gases were evolved to a small extent. He had in his mind such industries as used chloride of sulphur for the vulcanisation of india-rubber and other purposes. Where this substance was used on the large scale the neighbours might have cause for complaint, but it would be a difficult thing for those industries where the substance was used in but small quantity and intermittently to have to follow the larger works in putting up condensing plant. There would be an objection if the proposed Act was to be inoperative unless complaints were lodged, as a business in one locality might be seriously hampered to the advantage of a rival house where no legislative restrictions were in force.

Mr. RHODES thought the experience of the manure manufacturers answered Dr. Hurter's objection with regard to the best practicable means. No definite limit was fixed for those manufacturers who had their condensation to do in the best practicable manner. Had the limit been fixed early it would have been extremely difficult to conform to it. If it had been fixed at 0.2 grains per cubic foot total acidity in the mixer gases, some works would have conformed to it which were not condensing more than 60 or 70 per cent. of the gases from the mixer. Other works might be condensing 98 or 99 per cent. and yet have an escape with an acidity equal to 0.5 grain SO_3 per cubic foot. This was owing to the different construction of the plant, as when a fan was used to draw the gases from the mixers large quantities of air were sent through the condensers and diluted the gas, and went to reduce the total acidity per

cubic foot in the escaping gases. Where the chimney only was employed, this dilution of the gases was avoided. He (Mr. Rhodes) was also of opinion that gases should be scheduled instead of works, and maintained that even in the case of small industries such, for example, as the smelting of sulphate of lead from chamber bottoms, which caused a great nuisance, those who worked such processes should be compelled to condense their gases. Dwellers in Widnes sometimes experienced great nuisance from the smelting of these chamber bottoms. With regard to matters going before a judge and jury, a recent well-known case in which the defendants, who were supposed to have caused a great nuisance, were acquitted, demonstrated that under direction of a judge and before a jury everything would be thoroughly thrashed out.

Mr. FLETCHER remarked that as a judge and jury were the tribunal before whom cases in dispute must be brought for their decision, the facts, however technical, must be so marshalled and established as to be apprehended by them, convincing them even in the face of opposing evidence. It did not by any means follow, as had been suggested, that the aspirator and anemometer must be put on one side. These were required as means of bringing forward facts to convince the jury that the accusation or the defence was correct.

As to fixing a limit to air pollution, he would point out that the observance of the "best practicable methods" clause included the power of giving a definite limit. Numerical limits would grow in the hands of those who had to administer this clause.

It must be conceded that the best numerical standards that could practically be attained might vary under different circumstances, but experience and a continued effort to attain the best results would bring out a fixed limit clearly. Two figures had been mentioned as having been given provisionally, and they might still stand. They were, first, as to the amount of chlorine in a cubic foot of air issuing from a bleaching-powder chamber, that was given as five grains. Secondly, the amount of sulphuretted hydrogen that might be allowed to escape. This was fixed at 0. These figures came as the result of experience in the use of the best practical means for preventing the escape of these gases, and in this way from time to time other numerical standards would grow.

Prosecutions had been successfully carried through resting on this clause. The manufacturer was however, well sheltered from unwarranted attack. The difficulty was with the inspector, he had to marshal his facts and arguments in the face of opposition by witnesses on the other side so as to persuade the judge and jury that the best practical means had not been used. The manufacturers had the easier side of the argument to maintain; it was for the inspector to prove his case, and he was not likely to go into court unless he was quite certain of establishing it.

Cases that had recently been tried in Manchester might be cited as good instances of the protection afforded to manufacturers by the Government inspection. Nuisances were said to have arisen from certain factories which were under partial inspection, but the prosecution withdrew their claims against those portions which were thus under inspection, and rested it entirely on those portions which were not under Government inspection.

The difference between the inspection carried on under the Alkali Act and that of the sanitary officer, was that the Alkali Act empowered the inspector to see what was going wrong, so that he was often able to indicate means by which the source of complaint could be removed. Manufacturers were immensely shielded by the appointment of skilled inspectors who could investigate strictly into what was going on, and ascertain if the best practicable methods were employed for the suppression of nuisance.

As to the definition of sources of nuisance, Mr. Fletcher put it as an alternative; either that the gases which were to be subject of inspection should be named, or that all

manufacturing processes from which any noxious gas was liable to be discharged should come under the Act, a suitable definition of a noxious gas being given.

MR. NORMAN TATE said that it was undoubtedly desirable that further legislation should take place quickly. It was a great anomaly that one works should be debarred from turning out a certain gas whilst another works close to it could turn it out in quantity without interference. He was in favour of scheduling the gases instead of the works, and thought that, wherever possible, limits of escape should be distinctly mentioned; but he knew that it would be quite impossible in many cases to do this, and therefore a clause such as the "best practicable means" clause seemed absolutely called for. He decidedly objected to legal action being initiated by the representation of a certain number of neighbours or householders unless their complaints were most thoroughly sifted by competent inspection before legal action was taken. Any clause relating to such complaints from a number of householders or neighbours would require to be watched most closely and carefully framed, for it was very easy to get together the requisite number of complaints and put manufacturers to much inconvenience and expense.

MR. BUCHANAN and DR. CAMPBELL BROWN also supported the resolution which, on being put to the meeting, was carried unanimously, and a committee was appointed in accordance therewith.

EXHIBITION OF MODELS, &c.

DR. CAMPBELL BROWN exhibited several models of metallurgical furnaces which had recently been bought for the Chemical Department of University College from funds placed at its disposal by the City Council. These included models of an English lead furnace, a Belgian zinc furnace, a copper furnace, and a blast furnace, all of them being constructed so as to well illustrate the working of the several processes, and were of the same character as those supplied to the Mining Academy at Freiburg.

Meeting held Friday, April 8th, 1892.

MR. I. LEVINSTEIN IN THE CHAIR.

THE MANUFACTURE OF OXYGEN GAS.

BY FERDINAND FANTA.

As we know, atmospheric air is composed practically of four parts in volume of nitrogen to one part in volume of oxygen, and from this mixture the nitrogen alone cannot be removed because it has no inclination to combine directly or easily with any substance we know of, which does not also combine with oxygen.

Although mechanical means, such as forcing the air through porous material, india-rubber, metallic gauze, &c., have been experimented with, there does not seem to be any likelihood of such processes becoming practicable, in consequence of the great similarity of the two gases in respect of their physical properties, and of their density, which may be said to be approximately the same.

I now come to the method of separating oxygen from the atmospheric air by chemical means, and since, as I have just pointed out, no combination can take place with nitrogen, it becomes necessary to avail ourselves of the property of certain compounds of oxygen of absorbing certain determined quantities of oxygen which will be taken from the atmospheric air, and to again give up such oxygen under given circumstances, whereby the original lower oxide will remain as residue.

Two distinct processes, based on these reversible reactions, have been brought forward, one being based on the use of barium oxide which is due to Bunsen, the other based on the use of manganese oxides in combination with caustic soda, due to Tessié du Motay.

These are, so far as I know, the only two processes by which oxygen is obtained direct from atmospheric air without the intervention of any other chemical reaction, such as have been suggested for using oxides of lead, plumbates, &c.

The process of utilising barium oxide has been described at length in the Society's Journal (see L. T. Thorne, 1890, 246).

As you are no doubt aware, this forms the basis of the process known as "Brin's," and is, according to my belief, the only one which has till recently been applied on a somewhat large scale, and I am glad to take this opportunity of saying that some of the important applications to which oxygen, when produced on a large scale and a low cost, will be turned, may be to a certain extent attributed to the enterprise of the Brin Co., who, I understand, have of late years introduced a series of improvements, reducing, if not entirely removing, the inconveniences inherent to the process.

In reference to the second process, viz.: that of Tessié du Motay referred to above, Professor Mendeleëff expresses himself as follows:—

"As oxygen may become of considerable technical use from its capacity for giving high temperatures and intense light in the combustion of substances, its preparation directly from air by practical methods forms a problem whose solution many investigators continue to work at up to the present day. The most practical method is that of Tessié du Motay. It is based on the fact that a mass of equal weights of manganese peroxide and caustic soda, at an incipient red heat (about 300°) absorbs oxygen from air with the separation of water according to the equation $\text{MnO}_2 + 2\text{NaHO} + \text{O} = \text{Na}_2\text{MnO}_4 + \text{H}_2\text{O}$. If superheated steam at a temperature of about 450° be then passed through the mixture, the manganese peroxide and caustic soda originally taken are regenerated, and the oxygen held by them is evolved according to the reverse equation $\text{Na}_2\text{MnO}_4 + \text{H}_2\text{O} = \text{MnO}_2 + 2\text{NaHO} + \text{O}$. This mode of preparing oxygen

may be repeated for an indefinite number of times. The oxygen in combining separates out water, and steam acting on the resultant substance, evolves oxygen. Hence all that is required for the preparation of oxygen by this method is fuel and the alternate cutting off the supply of air and steam."

The only practical means of producing oxygen besides the "Brin" process are based on the Tessié du Motay process. Various attempts have been made in this respect, but seemingly with no effective result.

The difficulties which are met in this process, and which will be referred to more particularly in this paper, are of a complex nature, and it will be my endeavour not only to show the difficulties which have prevented the Tessié du Motay process hitherto becoming a commercial success, but also to indicate how these difficulties are being overcome in the process, of which I may claim some particular knowledge.

I now come to the different attempts to utilise the Tessié du Motay process. One patentee has suggested that, in order to render the material spongy and non-fusible, the sesquioxide of manganese should be fused, and then mixed with an admixture of caustic soda, also in a fused state. It was stated that the granular compound so formed would, if dusted over with black copper oxide, supply means of continuously producing oxygen by the alternate passage of air and steam.

Another patentee has advocated the use of permanganate admixed with kaolin, clay, &c., for the purpose of forming a kind of spongy brick, capable of yielding oxygen at different temperatures and pressures.

As to the first of these patents, I should say that, from experiments carried out with the greatest care, it is evident that the material is not rendered non-fusible, and that the addition of copper oxide is by no means to be commended in a process like this, since by doing so the fusing point of the compound is considerably lowered. From what I shall have an opportunity of putting before you later on, it is moreover, clear that it is a decided mistake to fuse the excess of caustic soda in order to get rid of the water contained therein.

As for the second patent, I may be allowed to say, while not doubting that oxygen may be produced by this process, and eventually even on a large scale, that there does not seem to be any reason why such an elaborate plant, necessitating, as it does, compressing and vacuum pumps, should be introduced for the purpose of utilising the remarkable properties of manganese oxides.

It has been my endeavour to study the causes of the non-success of the Tessié du Motay process (with the earliest stages of which I would here remark I was connected), and as a result of the researches to which I have been led, I find that the main points to be guarded against can fairly be said to be the following :—

It is all-important to render the material as granular as possible, and also to prevent it from fusing at a comparatively high temperature.

In the preparation of this material, I came to the conclusion that the most rational, and, I may say now, the *only* way of attaining this object, was to treat the material exactly in the same way as it would be dealt with during the process in the retorts. Accordingly, the material must, before being inserted in the retorts or utilised, not only be submitted to a temperature at least equal to that of the furnace in which it will be ultimately placed, but also that a sufficient quantity of moisture representing a similar amount to that to which the material will be exposed in the retorts, when steam is passed over it, should be introduced in the course of the preparation of the material. This, in other words, meant preparing the material according to a wet instead of a dry method, as had been suggested before.

Without going into the effects of such different preparations at the present, since I shall have to refer to them more fully in the course of the description of the process, I would simply say that, according to my views, manganate of soda

previously crushed by any ordinary mechanical means should be moistened with a small quantity of water, in which 5—10 per cent. of caustic soda has been dissolved, until a thick paste is obtained, and this mixing is best done by mechanical means, so as to ensure perfect homogeneity.

The paste is next submitted to slow heat, until complete evaporation has taken place. When the material is withdrawn from the shallow pan in which it has been evaporated, it is placed in a crucible where it is submitted to white heat. In this state the material is granular and spongy, and will not fuse, and it will readily be understood that, even if some amount of moisture were at any time brought into contact with this material, a simple evaporation will rid it again of the moisture, leaving it in its original state after preparation. This, however, is only one of the three difficulties to be overcome.

If air, charged as it always is, with a certain amount of moisture at a low temperature, be brought into contact with the heated material in the retorts, such moisture will cause spontaneous creation of steam, which, to say the least, would affect the oxidising power of the air by dilution and displacement. I say "the least" because, in my opinion, steam also acts as a de-oxidiser, and therefore the time requisite for the full oxidation of the material must be considerably increased, so much so, that after a series of reversed operations (oxidising and de-oxidising alternately) it will become necessary to oxidise the material by a prolonged passage of air in order to regenerate it.

It is moreover essential that the steam used in the de-oxidising period of the process, be introduced into the retorts in as dry a state as possible, and, if anything, at a higher temperature than that of the material, although repeated experiments have proved that it is sufficient to use steam at the temperature at which the retorts are being worked. This has, moreover, the advantage of facilitating the dissociation of the elements composing steam.

The result of the foregoing remarks is, that in order to maintain the material in its original condition, it is necessary to render the material non-fusible by the wet process, and to use in connexion therewith, air previously deprived of its moisture and heated to the temperature of the material in the retorts, for oxidising purposes in combination with superheated steam for de-oxidising purposes, and in that manner condensation in the retorts, and production of steam during the oxidising process are avoided, whilst the de-oxidation is facilitated considerably by the dissociation of the steam, and excess of moisture is guarded against during this second part of the process.

The formula by which the reactions take place, according to the Tessié du Motay process are as follows :—

According to the process before you these formulæ would read as follows :—

You will notice that the excess of caustic soda acts independently of the material itself, and, provided that only that amount of moisture be at any time allowed to enter the retorts, that can readily be absorbed, and can again be given up by such excess of caustic soda, the material will practically remain unaltered.

I had, perhaps, better at this stage explain the tracings which are before you, as it will enable me to more clearly convey to you the meaning of the series of operations which take place in connexion with the latter reaction.

I intend, after having given you a brief description of the apparatus, to enter into further details, if time permits, and

Fig. 2.

also to demonstrate on an experimental scale by means of the model before me, the mode in which oxygen is produced, which I trust will be interesting to you.

Description.

Fig. 2, is a general outline sketch diagrammatic of the whole arrangement illustrating the mode of operation.

Figs. 5 and 6 are longitudinal and cross sections of one of the dish-shaped retorts.

The same letters of reference indicate similar parts in the different figures.

As shown in Fig. 2, I construct an apparatus mainly composed of an outer rectangular or otherwise suitably shaped furnace, in which I place two or more series of retorts of suitable size and construction, but which I preferably construct as shown in Figs. 5 and 6. These are formed of a shallow rectangular tray or case made of cast iron, fireclay, or other suitable material, and are provided with a moveable cover or lid which can be hermetically fastened to the tray by means of bolts, screws, or other appropriate devices. The lower end of the tray is provided with a pipe *b*, running along the lower ledge of the tray, and the upper end of the tray is provided with a pipe *j*, communicating with the upper edge of the tray. Inside the trays are small wires *n* on which rests a perforated plate *o*, and on this perforated plate the manganoate (previously rendered non-fusible) is placed. The trays being filled with the material *p*, a second perforated plate *o'* is inserted, and the wires *n'* are fastened to same before enclosing the whole by screwing down the lid or cover *m*. Channels *x* and *y* are reserved in the moulding or casting of the trays by means of which the apertures *b* and *y*, are made to communicate with the free spaces left below and above the perforated plates *o* and *o'* respectively.

These retorts are placed at an incline of say 60°, and superposed on each other, allowing the heat of the furnace to circulate between them so as to equally and regularly heat the whole of the material with which they are filled.

Each of these retorts *a* and *a'* is provided with an inlet *b* at one end, and with an outlet *j* at its opposite end, and the connexions between the retorts are made in such a way that the inlet of the second retort is kept higher than the outlet of the first retort, so as to allow gases or steam, as the case may be, to ascend freely, owing to the difference of gravity consequent upon the heating of same as they pass through the retorts.

Fig. 2 shows two series A and B composed each of 24 such retorts, each of these series being formed of eight sets of three retorts, each of these eight sets being worked in parallel from one inlet collector H (and H' respectively) and each one of such sets of eight is also provided with an outlet collector I (and I' respectively).

I will now proceed to give full details of set A, it being understood that the second set B is in every way similar to set A.

The inlet collector H may be formed as shown in Fig. 2 of a cylindrical vessel, tube, or pipe, closed at one end, whilst at the other end (preferably the lower) it is provided with an air valve of sufficient internal section to provide the current of air necessary for eight retorts (in this case). The collector is moreover provided with eight small flanges, each of which is connected by means of a pipe to one retort. The eight pipes providing the necessary current of air to retorts Nos. 1 to 8 (in supposing the 24 retorts to be numbered in numerical order from 1 to 24, beginning with the lowest one) establish the communication between the collector and the lowest point of each of these retorts, whilst the highest point of each of these is put into communication with the lowest point of each of the next eight retorts by parallel junction pipes, and the highest point of this second lot of eight retorts is again put into communication with the lowest point of the third lot of eight retorts, whilst the highest point of these communicates with the outlet collector

I in every way similar to the inlet collector, with the exception that the air valve in this case is fixed on its upper end.

It will be understood from the above, and in referring to Fig. 2, that eight distinct series, each composed of three retorts, viz., 1, 9, 17; then 2, 10, 18, and finally 8, 16, 24 are formed; that these eight series are supplied simultaneously and that the passage of air through these 24 retorts is controlled by the two air valves K and L. The collector H is, moreover, provided with a small valve *f* for the inlet of steam, and the outlet collector I is provided with a valve *g* for the outlet of oxygen.

On the other hand the furnace contains two series of vertical pipes E and E' composed each of a suitable number of these, connected together at the upper end by horizontal pipes M and M', and at the lower end with similar connecting pipes N and N'. The latter are connected with the inlet valves K and K', whilst the upper pipes M and M' are connected together and supplied with air by means of a fan, blower, or similar appliance.

These two sets of pipes E and E' are filled with lime, chloride, or suitable material, for the purpose of absorbing the moisture of the atmospheric air which is forced through them, previous to its entering the retorts containing the material, and in this way such air is heated, and reaches the inlet collectors in a dry state, and at the same temperature, as that of the material in the retorts. These two points are essential to give the air its full oxidising power, as otherwise the moisture contained in same would create a spontaneous production of steam (thus tending to partly de-oxidise the material) on its coming into contact with the hot material in the retorts, and to this the unsuccessful attempts made up to the present time with the Tessié du Motay process may largely be ascribed.

As, however, the continuous passage of damp air over the same lime would speedily render some inactive, owing to its becoming saturated with moisture, each of the entrance pipes M and M' is provided with a two-way valve O' O², Fig. 2, by means of which each of the two sets E and E' can either be put into communication with the blower or can be thrown open allowing the moisture absorbed by the lime, whilst the damp air was passing over it, to evaporate, thus regenerating the lime, and rendering it serviceable during the next cycle.

It will be further understood that by means of these two double-way valves, one of the sets (E for instance) is traversed by air on its way to the valve K, such air being thereby dried and heated, whilst the other set E' throws off by evaporation the moisture which it had retained from the air passed through it on its way to the valve K' in a previous operation. The action of the two-way valves will be readily perceived, and the way they are operated upon by the mechanical device explained hereafter, is identical to that by which the air valves themselves are reversed.

In addition to the two sets of retorts containing the material to be oxidated and de-oxidated alternately, and to the two sets of air heating and drying pipes; the furnace also contains a continuous coil, serpentine, or similar series of pipes traversed by steam derived from any suitable boiler, the object of such coil, &c. being to superheat the steam necessary for the de-oxidating of the material in the retorts, and to thus decompose same into its constituent elements previous to the admission thereof to the steam valves *f* and *f'*.

The operation takes place as follows:—

The dish-shaped retorts having been filled with material specially prepared so as to render it non-fusible, in accordance with specification named before, and the furnace having been set to work until a regular temperature of between 400° and 450° has been attained throughout, air is forced by means of the blower through set A, this air passing through the horizontal pipe M into the series of vertical pipes E, where it rids itself of its moisture and becomes heated, enters the collecting pipe N, and its temperature is still further increased in passing in the fireplace until it reaches the inlet valve K. Entering the

inlet collector H it finds its way into the eight lower retorts, oxidates the material contained therein, and passes on to the next eight retorts by means of communicating pipes, and then again passes from these eight retorts to eight more, finally reaching the outlet collector I in the form of freed nitrogen, the oxygen having been retained by the material.

Whilst this operation has been going on, the valves *f* and *g* have remained closed.

In the meantime, and simultaneously with the passage of air through the retorts of the series A for the purpose of oxidating the material therein, the following has been taking place in the series B, viz:—

The double-way valve *O'*, Fig. 2, between the blower and the pipe *N'* being placed in such a position that communication is intercepted between the blower and the set *E'* of drying and heating pipes, and consequently so that the moisture contained in the lime of these pipes can freely evaporate passing into the open air, and the valves *K'* and *L'* being closed, the superheated steam has been allowed to enter by means of the valve *f'*, whence it enters the retorts 1 to 8 of the series B, de-oxidising the material contained therein, then passing from the highest point of these retorts to the lowest point of retorts 9 to 16, where it de-oxidates further material, and so on until the oxygen thus freed, in addition to that liberated from the last eight retorts, enters the outlets collector *I'*, and leaves same through the valve *g'*.

It is clear from the above that the inlet and outlet air-valves *K* and *L* of one series, and the steam inlet-valve *f''* and the oxygen outlet *g'* of the other series, will have to be kept open; whilst, on the contrary, the steam inlet-valve *f* and oxygen outlet *g* of the first series, and the inlet and outlet air-valves *K'* and *L'* will have to be kept closed, when, as is supposed in this case, the series A is being oxidised, the series B being simultaneously de-oxidised, and, further, that the position of each of these valves will

have to be reversed when the oxidation of the series A and the de-oxidation of the series B has been completed.

The reversing of these valves would naturally have for effect to allow the superheated steam to pass over the material of the series A which has just been oxidised, thus de-oxidising it again, whilst the dry-heated air passing over the material of retorts B, will re-oxidise the material, which, during the previous operation had given up its oxygen under the influence of steam.

It would seem, at first sight, that if by any mechanical arrangement the spindles of the eight valves (viz. four air and four steam oxygen valves) were to be connected, so that *K*, *L*, *f''*, *g'* are open, and *K'*, *L'*, *f*, *g* are closed, the reversing of one of the spindles, or of the shaft to which the eight spindles were geared, would produce the desired effect of alternating the flow of the fluids.

This is, however, not the case, and would, at all events, necessitate an interruption in the production of oxygen, whilst it would entail a considerable loss of the gas itself, in consequence of the de-oxidising steam entering the retorts before the air valves have been entirely closed; and in supposing even that the reversing of the valves takes place with sufficient rapidity to avoid waste of gas, then again the air in the retorts would become mixed up with the oxygen, thus considerably impairing its pureness.

What is needed, on the contrary, is that in the series which has been traversed by air, the inlet be closed separately, and that a certain interval be allowed for the air or nitrogen to find its way out into the atmosphere (this being facilitated by the difference of gravity of such air in the retorts and the outer atmosphere, and by the inclined position of the retorts and communicating pipes) before the outlet valve is closed, thus reducing the vitiating element to a minimum, whilst retaining in the retorts the full quantity of the oxygen which the material has been capable of absorbing.

On the other hand, it is essential that the valve permitting the outlet of the oxygen be opened before the valve

Fig. 5.

Fig. 6.

regulating the inlet of steam is opened, so as to facilitate the passage of the superheated steam over the material, and allow the same to traverse the retorts with the greatest possible rapidity, since the effect of hampering it in any way would be to unnecessarily condense the same, consequently moistening the material, which should be avoided.

The preceding remarks, which refer to the set which is being de-oxidised, also apply to the second set, the reversing of the valves of which has for its object to allow the oxidising air to pass over the material which has just been de-oxidised. Here it is important to close the inlet of steam, to allow an interval between the closing of the first valve and the closing of the outlet of oxygen, so as to fully exhaust the oxygen that can be freed, as otherwise the premature opening of the air valves, would amount to a waste of oxygen which would be carried away with such air; then only open the outlet of air, when any moisture retained in the retort will find its way out, and to finally open the inlet of dry hot air for oxidising purposes.

This latter point is rendered all the more important by the fact that the air introduced into the retorts for oxidising purposes would, if carrying moisture with it, have a de-oxidising power on the material instead of an oxidising power, as it would practically act like steam itself.

It is consequently necessary that the valves should be made to act in the following rotation:—

In series A-K closes; L closes; *g* opens, *f*' opens; whilst at the same time, in series B, *f*' closes, *g*' closes; L' opens, K' opens.

From this it will be seen that:—

K closes when *f*' closes,

L closes when *g*' closes,

L' opens when *g* opens,

K' opens when *f* opens,

and, *vice versa*,—

K' closes when *f*' closes,

L' closes when *g* closes,

L opens when *g*' opens, and

K opens when *f*' opens.

To obtain this object I devise a mechanical arrangement (Fig. 2), mainly composed of a horizontal shaft C, provided in its centre with a screwed part, the thread of which engages in a threaded plumber block E², and this shaft can be acted upon either by a straight belt or by a cross belt. When the cross belt is made to act, the shaft revolves from left to right, and is made to travel longitudinally from left to right also. On this shaft four loose double chain wheels, kept in position by lateral supports, are connected by means of chains with the spindles of the valves as follows:—

One of the wheels of the double chain wheel O acts, when same is thrown into gear, directly on the spindle of the valve K, thereby closing same, whilst the second wheel of the double chain wheel O acts on the small shaft *h*', the opposite extremity of which closes at the same time the inlet of steam *f*' by means of the gearing *h*² and *h*³.

The double chain wheel O which, as stated before, is loose on the shaft, is brought into action in consequence of the feather *h* of the shaft C becoming engaged in the key-way of the wheel, and acts upon this wheel until the shaft C has travelled sufficiently to the right, when the feather becomes disengaged, and the wheel becomes loose again. The thickness of the wheel and the pitch of the screw, as well as the respective diameters of the chain wheels, are so calculated that the valves are closed or open, as the case may be, when the feather has done its work. The shaft then continuing its course, occasions the feather *i* to engage in the next double chain wheel P, which is acted upon in the same way, closes the valve L and *g*', whilst the shaft still moving from left to right, brings the chain wheel Q into operation by means of the feather *k*, thereby opening the valves L' and *g*, and finally, and in the same way, the feather *l* acts on the double chain wheel V, which opens the valves K' and *f*'.

The shaft C is now at the end of its course, and is made to throw the cross belt out of gear, and is thus stopped.

When the reversing of the valves becomes necessary, the straight belt is made to act upon the shaft C, when same turning in the opposite direction, viz. from right to left, occasions the shaft to travel longitudinally in the opposite direction, thus coming back when the feather *l* acts on the double chain wheel V, then feather *k* on double chain wheel P, and, finally, feather *h* on double chain wheel O, thus reversing the respective valves in their proper rotation, as will be understood on referring to the drawing and to the table above. When the shaft C has again come to the end of its course on the return it throws the straight belt out of gear, whereby it is stopped, being thus once more in its original position.

The throwing into gear of either the cross belt or the straight belt is obtained by the physical state and condition of the fluid coming from the outlet valves *g* and *g*', as explained.

The oxygen, on leaving the valves *g* and *g*', is conveyed to two cooling appliances, R and R' (Fig. 2), the cooling apparatus R being connected with outlet valve *g*, and R' being connected with *g*'. At the lower extremity of the cooling apparatus, where the oxygen leaves same and is carried to the washing vessel W (Fig. 2), by means of the pipes *r* and *r*', two branch pipes *s* and *s*' are provided for, and these are made to communicate to the lower end of two cylinders S and S'. Each of these cylinders is provided with a float V, V', connected by means of a vertical guide-rod to a balance connecting the two rods. The two ends of this balance are, by means of a crank, chain, or otherwise, connected with the shipping fork of a friction clutch, which acts on a pulley, V, V', the boss of which is provided with a key, engaging in a groove of the shaft C, on which they are loose otherwise, so as to allow same to travel longitudinally. The gas having been passed through the washer, leaves same by means of the small pipe *t*, which conveys same to the gasholder for storage purposes.

Midway of the branch pipes *s* and *s*' are inserted two diaphragms (G, G' Fig. 2) valves constructed as follows:—

An outer casing 1, 1 (Fig. 7) is divided into two compartments by means of an elastic diaphragm or plate, so as to form two chambers. The upper chamber 7 is provided with an inlet 3, and an outlet 2. The diaphragm plate 6, forms a hermetic joint B with the flanges of the upper and the lower chambers. The lower chamber has an inlet 4, and outlet pipe 5, there being a valve seat and valve 9, between this inlet and outlet, and this valve is fastened to the centre of the diaphragm plate 6 by means of the valve spindle 10, which is counterbalanced and regulated by means of the adjustable spring 11, and the pressure can be set by means of the screw pin 12.

These valves are placed between the steam superheaters and the steam inlets *f* and *f*', of the two sets A and B, in the following manner:—

The steam coming from the superheater enters the pipe 4 of the lower chamber, and passing through the valve 9 leaves the chamber at 5 on its way to the retorts. The spring 11 is set so that the valve is slightly open when oxygen is evolved from the retorts.

The entrance pipe 3 of the upper chamber is connected with the upper part of the branch pipe *s*, coming from the cooler, and the outlet 2 of the same chamber 7 is connected with the vessel S containing the float *v*.

When, and as long as oxygen is evolved from the retorts, this oxygen finds its way to the washing vessel without entering chamber 7, but as soon as steam passes through the cooler, same becomes condensed and the water resulting therefrom, on reaching the diaphragm plate, causes same to contract, and the pressure thus acting on the valve 9, closes same and prevents any more steam from entering the retorts, whilst any steam which is still contained therein distills over to the cooler, and becoming condensed in its turn creates a vacuum in the cooler which causes the float *v* to be lowered owing to the water contained in the vessel S being taken up through suction pipe *s*, where it remains until the next cycle comes into operation.

The two valves *b* and *b'* are identical in construction, and their respective connexions are similar in every respect.

The operation of the float and gear arrangement is as follows:—

As long as oxygen gas is liberated from one of the sets, say *A* of retorts, it finds its way to the cooling apparatus *R*,

through the pipe *r*, and the washer *W*, into the gasholder. As will be seen the floating arrangement has not in any way been brought into action so far. The liquid in both cylinders and the floats therefrom remaining at the same level, and in this position both shipping forks *T* and *T'* are in the vertical position, both pulleys being consequently out of gear, and the shaft *C* stationary.

Fig. 7.

When however the oxygen of the series *A* has been exhausted by the passage of the requisite quantity of steam, the fluid leaving the valve *g* is no longer oxygen only, but actual steam, which although superheated contains all the constituents of steam, and in fact is nothing but steam. Now, as soon as this steam enters the cooling apparatus *R*, this cooling apparatus begins (in consequence of the large available cooling surfaces) to act as a surface condenser of the steam, thereby creating a vacuum owing to the fact that the return of the gases from the gasometer is rendered impossible; on the one hand by means of check valves, whilst on the other hand the specially constructed diaphragm valves, *G*, *G'*, shown in Figs. 7 and 2, inserted on the pipe leading the steam from the steam superheater to the retorts containing the material automatically regulate or determine the entrance of steam into the retorts. This valve is acted upon and closed as soon as the condensation water coming from the inside of the refrigerator tubes is brought into contact with the upper surface of the diaphragm plate of this valve; and since the condensation water is led on to the diaphragm as soon as steam passes in the refrigerator instead of oxygen, the entrance of the steam into the retorts is stopped immediately.

In consequence, however, of the considerable difference of temperature between the steam remaining in the retorts and that contained in the pipes of the refrigerator, the

steam distils over to the refrigerator, where it becomes condensed, thus creating a vacuum, which is not only an advantage in respect of the retorts being freed of unnecessary moisture, but this vacuum is also utilised for acting on the floats, as it is made to draw away part of the water contained in the vessel *S* by means of the pipe *s*, and in this way float *v* is lowered, made to act on the crank *w*, and thus on the shipping fork *T*, which engages the pulley *V*, provided with a cross belt, by means of which arrangement the shaft *C* is made to travel from left to right, reversing the position of the valves as explained before. When the shaft is at the end of its course, the friction clutch of the pulley *v* is thrown out of gear by the shaft itself, thus stopping same, and the float is again rendered independent.

The series *B* is thereby brought under the influence of steam, in the stead of the series *A*, and as long as oxygen is being liberated the floods remain inactive, and the shaft *C* stationary. As soon, however, as the oxygen becomes exhausted, the same action as that explained before with reference to the float arrangement in connexion with the cooling apparatus *R* takes place in the float arrangement *S'*, and thus operates on the shipping fork *T'*, and on the pulley *V'*, which is acted upon by the straight belt, thus making the shaft *C* come back to its original position, reversing the valves on its backward course.

The change of cycles is thus produced automatically, and regulated by the nature of the fluid leaving the retorts. The main object and result obtained thereby is not only a saving of labour, but is principally to avoid an excessive strain on the producing power of the retorts, and thus the material does not become loaded by any unnecessary moisture, whilst perfect regularity of the working of cycles is secured.

DISCUSSION.

Dr. BOWMAN said that a most important point in the process was, that the air and steam came in contact with the materials at the same temperature, whereas in the old processes the air and steam were at different temperatures. In this case, however, it might, without injury, vary in the furnace or retort, since the pipes travelled side by side. The reaction thus took place with greater certainty, and the materials, instead of deteriorating, retained their properties however long they were in use. The process was automatic, and a temperature of about 600° which could be obtained as waste heat, was quite sufficient to evolve oxygen and keep the material in a fit state for the process. When the steam had done its work it ceased to be decomposed, and passed through the pipes towards the cooler. The materials used were very cheap; and when once charged the operation went on night and day. The gas contained about 95 per cent. of pure oxygen as it issued from the machine.

Mr. WATSON SMITH said he had seen Mr. Fanta's model plant at work, and was astonished at the rapidity with which the gas was evolved. He had asked Mr. Fanta to let him see the experiment carried out in his own laboratory, in an ordinary glass tube placed in a combustion furnace, so that he might prepare the materials with his own hands according to the prescription. The success of such an attempt, he had found, depended to some extent on the mass of the material, and as a glass tube continually cracked, a copper tube like that before them was substituted. Complete success had followed the trial. He thought it plucky of Mr. Fanta to dare to attempt to make oxygen gas in this laboratory model before his audience, by a reaction in which the question of mass was certainly concerned to some extent, and in which the process was also a reversible one. Mr. Fanta had done this, however, at his urgent suggestion, and he could vouch for the material, for he (the speaker) had prepared it with his own hands. The part of the process which had at first excited his incredulity, was that in which it had been alleged that the material was rendered *more infusible*, by first intimately mixing it with some caustic soda. He had a lively recollection of the fate of caustic soda ash in the soda-ash furnaces, when the material contained say 13 or 14 per cent. NaOH. He was once connected with the old Prestolee Alkali where a very white caustic ash, which contained as much as 16 to 17 per cent. NaOH, was skilfully made for rag bleaching in paper works; and he well remembered the difficulty of furnacing the material owing to the greatly increased fusibility due to such a high percentage of caustic soda. Here then was a very unexpected physical condition, superinduced by the addition of a substance from which the opposite result would have been expected.

The CHAIRMAN said in his opinion the demonstration which Mr. Fanta had brought before them was another forcible illustration that chemical industries depended not only on chemical knowledge, but largely on chemical engineering. As a chemical invention there was nothing new in the process described, and all that Mr. Fanta had done was to resolve the mechanical difficulties which stood in the way.

Mr. FANTA said he started with caustic soda and finished with an excess of it. It had been suggested that the caustic soda should be fused and then put into the retort. If that was done, after a time the material became absolutely unfit for use. In this process the caustic soda, added in the solution was evaporated with the manganate, and then submitted to heat. In that condition the material did not

fuse again, but would stand white heat without fusing. The theory of this was verified by the reaction which he had put down, and this was again verified in the process itself. There was one important point, and that was, if the manganate in the retorts were wholly deoxidised, the re-oxidation did not take place freely—in fact, in some cases it would not take place at all. He found that the proportion of manganate in the retorts did not exceed 40 per cent., and this was entirely different to what really happened in other processes. The proportion of the materials was one of the essential points.

Dr. GROSSMANN said he had been closely connected with the oxygen industry nearly all his life. If there were any fault which he could find with the apparatus it was that it was too ingenious, but, as Dr. Bowman had stated that it did not get out of order, this was all the more creditable. He should like to ask Dr. Bowman if the temperature he gave were Fahrenheit or Centigrade?

Dr. BOWMAN: Between 600° and 800° F. This low temperature was one of the advantages of the process, because it enabled them to use iron pipes without fear of deterioration.

ON SOME OF THE RISKS ATTENDING THE USE OF HIGH-PRESSURE GASES.

BY C. F. RUDENBERG, B.S.C., AND W. E. HEYS.

THE newspapers have made us familiar with several cases of explosions attended with most regrettable consequences, which have occurred in the use of high-pressure gases. An investigation of the causes which have led up to these explosions reveals nothing which might not have been predicted, but much which was not expected.

We will ignore such explosions as have their origin in the use of defective material and workmanship, and in insufficient strength, since these causes are purely mechanical and can be avoided by ordinary prudence. But we may remark that calculations for strengths based on the static pressure of the gas to be employed, will be hereinafter shown to be greatly misleading and to give far too low values. The example of exploded apparatus on the table will demonstrate to you the almost criminal negligence which sometimes occurs in the manufacture of fittings for high pressures, and the fatal folly of users who, regardless of risks, prefer what is cheap to what is good.

In the use of high-pressure gases, they are generally contained in steel flasks, fitted with a valve at the nozzle. To this nozzle the service pipe is secured, which is usually fitted with a regulator valve and a pressure gauge. We may usefully limit our observations to such an arrangement, as it will teach us all that is necessary.

Our first observation is that immediately on the opening of the valve, no matter how carefully and gradually this may be effected, the needle of the pressure-gauge flashes suddenly to the point on the dial indicating the pressure in the flask. The same result occurs even if the gas is withdrawn by being caused to pass through the finest hole which can possibly be drilled, say less than the tenth of a millimetre in diameter.

Secondly, we observe that the service pipe, pressure-gauge, and regulator valve, enclose a rather considerable air space to which the compressed gas has access.

From these conditions we deduce—

(a.) That ordinary time values must not be regarded, the phenomena being instantaneous.

(b.) That owing to the enormous velocity of the issuing gas, great friction must arise and increase the temperature of the gas.

(c.) That the air enclosed in the fittings must be instantaneously compressed to at least the same pressure as the gas in the flask.

(d.) That this instantaneous compression of the air must result in an increased temperature.

(e.) That owing to the heat of friction and of compression, the mixed gas and air must, instantaneously, have a highly exalted temperature.

(f.) That this increase of temperature is sufficient, at less than 100 atmospheres pressure, to dissociate the elements of hydrocarbons. We will illustrate this experimentally with atmospheric air at about 80 atmospheres pressure, which you will see is quite sufficient to reduce chips of wood to ashes.

(g.) That in the event of the compressed gas being oxygen, this gas will instantaneously combine explosively with the dissociated elements, forming water and carbon dioxide. The increase of pressure (e) by heat and (g) by explosion, are additive.

It will, from the foregoing, be obvious that even in the case of an inert gas like nitrogen or CO_2 the actual pressure to be instantaneously borne by the fittings is very far indeed in excess of the pressure in the flask.

It is very possible and easy to adopt precautions of an elementary character which will eliminate all possible risks of danger from explosion.

These precautions are briefly:—

(1.) Careful avoidance of even a trace of oil, or of any hydrocarbon in any of the fittings, or anywhere whence it may leak, penetrate, or be conveyed to the fittings.

(2.) Closing the orifice through which the gas must pass from the flask, by means of a compact porous septum, so as to prevent any outrush of gas.

(3.) Sufficient strength of material and first class workmanship.

(4.) The avoidance of a closed casing for any part of the fittings, since a minute leak into the casing may induce an explosion; sufficient pressure and heat being accumulated before even a weak casing can give way. In the case of a casing for a pressure-gauge, light flaps are employed, to close suitable openings formed in it. This may be combined with a second porous septum completely filling the inlet to the gauge.

It is very usual with some makers to test their gauges by means of an oil pump; such makers' gauges should be avoided for high-pressure gases.

An additional precaution may be found in making all the air spaces in the fittings as small as possible, since the quantity of the air compressed is one measure of the amount of heat developed in the act of compression.

We desire particularly to call attention to two remarkable characteristics of explosions which have been observed as arising from the presence of oil. These are, their intensity and their limited localisation. An explosion of mixed hydrogen and oxygen in well made fittings is comparatively innocent, and may take place without any serious damage at all pressures. In the case, however, of an explosion owing to the decomposition of oil, such as we have before spoken of, the explosion is of the most intense character and attended by a temperature sufficient to fuse a considerable mass of steel or brass: whilst it is limited in its effects to a very small portion of the space in which it may occur. Thus, when the explosion has taken place in a tube with a quarter-inch bore, the explosion has been limited to some three or four inches in length, where the walls of the tube have been so fused as to increase the bore to about half an inch, and the tube itself has been completely ruptured. At the same time a pressure-gauge attached to the tube at a short distance has not been damaged. Probably some members of the Society may be tempted to investigate this part of the subject more fully. It may be new to some of them that ordinary oil may under such simple conditions become an explosive of extraordinary power.

THE ANALYSIS OF SNOW FROM THE NEIGHBOURHOOD OF CHEMICAL WORKS AND VARIOUS OTHER PLACES.

BY J. CARTER BELL, A.R.S.M., F.I.C. ETC.

THE Corporation of Manchester, in consequence of complaints from people in the neighbourhood of Mr. Levinstein's works, brought an action against him at the last Manchester Assizes for emitting noxious acid and other vapours from his works, thus polluting the atmosphere. As the ground all round the works was covered with snow, I thought it a good opportunity to collect some, and compare it with the snow which I collected from other places far removed from chemical works.

Place.	Parts per Million.		Chlorine as Chlorides.	Sulphuric Acid as Sulphates.
	Free Ammonia.	Fixed Ammonia.		
1. Corporation St....	0.85	1.00	76.0	3.40
2. Exchange Station.	1.50	0.75	108.0	2.70
3. Broughton Bridge	2.60	1.25	95.0	3.60
4. Broughton Park...	0.200	1.00	7.0	2.90
5. Sewage Works....	0.50	1.50	8.0	4.90
6. Garden on Cliff...	0.60	1.00	7.0	3.30
7. Kersal Moor.....	0.30	1.00	5.0	2.90
8. Owens College....	2.00	1.40	17.0	4.70
9. Outside Mr. Levinstein's Works.	1.00	0.50	8.0	1.80
10. Bank opposite chimney.	0.370	1.00	6.0	3.20

None of the samples contained any free acid, but the chlorine in Nos. 1, 2, and 3, is excessively high. I can only account for this by assuming salt to have been thrown upon the streets as is the custom in Manchester. All the other samples were collected from the upper surface of undisturbed snow. These analyses with other evidence actually proved that the air in the neighbourhood of the chemical works was purer than that found in the Manchester streets.

NOTE ON THE ACTION OF FROST UPON COTTON.

BY C. F. SEYMOUR ROTHWELL, F.C.S.

FROM the literature published on this subject one obtains the idea that cotton is tendered by frost. Hummel, in his "Drying of Textile Fabrics," says, "that although the evidence on this point is quite conflicting, it is quite conceivable that the crystallisation might act injuriously in a mechanical way, and that the atmospheric ozone might also exercise some slight destructive influence." This uncertainty is no doubt due to the fact that until recently no reliable machine for testing the strength of the cloth was available.

The following experiments were made to decide this question:—Two pieces of "madder-bleached" cloth, one of good quality and the other of very poor quality, were placed in water for 10 minutes, withdrawn, and, without squeezing, hung up, full width, the thermometer registering four degrees below zero Centigrade. The cloth was quite stiff in three minutes, and although the temperature never rose higher than -3°C ., in three hours the ice had completely evaporated leaving the cloth quite dry. The strength of the cloth which had been frozen was then tested with Goodbrand's "Dead Weight Cloth Testing Machine," against some of the same cloth in its original condition, when the breaking weight was found to be identical in both cases.

When carefully used the machine is accurate to within \pm per cent.

The above trials were repeated, but when the ice had evaporated—which generally took three to four hours at -3°C. to -4°C. , the cloth was dipped in water and hung out again, this being repeated four times, making the total time the cloth was frozen about 16 hours. The strength of both qualities of cloth was also found in this case to be equal to the original cloth.

From these trials it is evident that cotton is not "tendered" by the freezing of water within it, at any rate not when in the open width.

If the fibres were bound or held in position to a greater or lesser extent, such as obtains in the case of the pieces near the bottom of a waggon-load of cloth when frozen, probably the cloth might be weakened mechanically by the crystallisation of the water, but, although I have only made a few trials in this direction still they indicate that the cloth is practically uninjured.

The prevailing opinion that cloth is weakened when it is frozen has no doubt arisen from the fact that when the fibres are frozen stiff they are easily snapped; but any stiffening body, such as gum, &c., will have the same effect, and this has obviously nothing whatever to do with the actual strength of the fibre.

Meeting held Friday, February 5th, 1892.

MR. IVAN LEVINSTEIN IN THE CHAIR.

ON THE ALUMINO-FERRIC PROCESS OF SEWAGE TREATMENT.

BY G. Sisson, JUN.

SEVERAL important omissions in the papers of Messrs. Grimshaw and Barrow, in the January number of the Journal, appear to have passed unnoticed. For example, on page 4 there is the following:—"For the purpose of comparing the action of clarine with that of other precipitants and processes, I have been able to obtain figures ready to hand in relation to the International, Electrical, and Lime processes. These are the only processes which can be said to be in the field for the purification of sewage."

This last sentence shows a remarkable oversight on the part of the writer, as over 30 towns and villages are now using a process not mentioned in the above, viz., the "Alumino-ferric," which is treating at least 20 million gallons of sewage daily.

On page 5, sulphate of alumina is confused with "alumino-ferric." Although the latter contains the former it also contains, as its name indicates, an iron salt, the proportion being sufficient to take up any traces of sulphuretted hydrogen present in ordinary town sewage.

Mr. Grimshaw (page 11) claims that persalts of iron act as carriers of oxygen to oxidise the organic matter of the sewage, by a so-called catalytic action, that is to say, ferric oxide (of course hydrated) becomes ferrous oxide, having given up oxygen to the organic matters; then it re-oxidises to ferric oxide and so on.

No evidence whatever has been brought forward to support this view. No experiments are cited to prove such a reaction, and supposing the whole of the surplus oxygen of ferric hydrate to be available, the amount is quite insufficient to deal with the organic matter present in the sewage. For example, in the addition of 5 grains of Fe_2O_3 per gallon of sewage only 0.5 grains of oxygen are available for this purpose, while sewage such as that of Salford will absorb 5 grains of oxygen per gallon, viz., 10 times as much. Moreover, when a reagent is added to sewage the precipitate formed is soon carried down to the bottom of the settling tank, and is thus removed out of the field of action.

With reference to the cost of different processes, the statements on pages 6 and 7 of the Journal are very confusing; e.g., on page 6 the cost of the alumino-ferric

process is stated to be 67s. per million gallons, while on page 7 it is put down at 75s.—apparently a mistake. The calculations must be based on erroneous data; at all events neither of the figures given is correct. On the same page, after the table of comparison, it is stated that all except the first and last processes propose to filter, thus including the "alumino-ferric" as a process where filtration is required. As a matter of fact filtration is not required, and is indeed unnecessary.

With reference to sludge, the weights given on page 7 also appear to be incorrect. No actual measurements of sludge were taken during the Salford trial with "alumino-ferric," and the figures given must therefore have been obtained by some method of calculation not stated. The lime process, which, it is generally admitted, gives a maximum amount of sludge, is actually credited with a less quantity than that produced by alumino-ferric, thus showing the incorrectness of the figures.

Hon. Local Secretary and Treasurer:

Dr. J. T. Dunn, The School, Gateshead.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies and will take office in July next: Chairman: A. Allhusen, Vice-Chairman: John Pattinson. Committee: John Morrison, W. A. Rowell, and T. W. Stuart.

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

Meeting held in the Durham College of Science,
Newcastle, on Thursday, April 7th, 1892.

MR. JOHN PATTINSON IN THE CHAIR.

NOTE ON THE PREPARATION OF SAMPLES OF RICH ARGENTIFEROUS LEAD FOR ASSAY.

BY JOHN PATTINSON, F.I.C., AND H. S. PATTINSON,
PH.D., F.I.C.

It has been found that the most satisfactory method of obtaining an average sample of pigs of rich argentiferous lead—containing from 100 to about 1,000 oz. of silver per ton of lead—is to saw each pig through with a circular saw. The fine particles produced by the saw, termed "sawings," are collected, and from them the samples are drawn to be sent to the assayer.

Assays of rich argentiferous lead are best made upon from 200 grains to half an ounce of lead, but such a small quantity of the sawings as this cannot be relied upon to represent the whole bulk of the sample, because of the large size of some of the particles. This difficulty, however, is easily overcome by melting up either the whole of the sample or such a quantity of it as can be relied upon to represent the composition of the whole, and casting the lead into small cakes or "buttons" from which portions weighing from 200 grains to half an ounce can then be cut for assaying. We find that from a sample of sawings of the usual size a button or small bar fairly representing the sample can be cast from about 2,000 grains of the sawings.

When the sawings are melted the button of lead obtained invariably weighs less than the weight of sawings taken,

This loss of weight is partly due to the oxidation of the impurities contained in the lead, which separate as dross or are volatilised during the process of melting. The remaining lead is consequently enriched in silver by the removal of these impurities and the assay obtained from this lead is higher than the true assay of the parcel of bars from which the sawings were taken. A correction must therefore be made upon the assay for this enrichment in order to arrive at the true assay of the sample.

The total loss of weight on melting the sawings is, however, not wholly due to oxidation and volatilisation of the impurities, but is partially due to the combustion of the oil that is upon the surface of the sawings, which has been introduced into the sample by the necessity of using oil to lubricate the circular saw. To correct the assay of the melted lead by an amount corresponding to the total loss of weight on melting the sawings, would therefore be obviously wrong, since a portion of this loss is due to oil in the sample which was no part of the original bars of lead. The percentage of oil in the sawings must therefore be ascertained and deducted from the total percentage loss on melting the sawings.

We determine the oil in the sawings by washing 1,000 grains of them with ether, filtering into a tared flask, evaporating the ether, and weighing the oily residue remaining in the flask.

With some classes of lead the loss of weight, due to oxidation and volatilisation of the impurities, when the sawings are melted alone, is very considerable. We find that a very convenient way of diminishing this loss is to add a little potassium cyanide to the sawings when they are being melted. We use for this purpose about half an ounce of ordinary commercial potassium cyanide to 2,000 grains of the sawings and the melting is made in a fireclay crucible.

As an example of how the loss is diminished, the following instance may be cited:—

4,000 grains of sawings melted alone lost in weight
60 grains = 1·5 per cent.
2,000 grains of the same sawings melted with KCN lost
16 grains = 0·8 per cent.

The percentage of oil in these sawings was determined and found to be 0·52 per cent. Deducting this amount from each of the above total losses we find that the loss due to oxidation and volatilisation is—

When the sawings are melted alone, 0·98 per cent.

When the sawings are melted with KCN, 0·28 per cent.

In this instance, therefore, the loss due to oxidation and volatilisation was $3\frac{1}{2}$ times greater when the sawings were melted alone than when they were melted with potassium cyanide.

The following table gives some examples of the results obtained with several samples of sawings when potassium cyanide was used in melting them:—

	Total Percentage Loss, including Oil.	Percentage Loss due to Oil.	Percentage Loss exclusive of Oil.
1. First trial	0·78	0·52	0·26
Second trial	0·80	0·52	0·28
2. First trial	0·35	0·11	0·24
Second trial	0·35	0·11	0·24
3. First trial	0·50	0·32	0·18
Second trial	0·51	0·32	0·19
4.	0·30	0·15	0·15
5.	0·30	0·13	0·17
6.	0·31	0·12	0·19
7.	0·38	0·15	0·23
8.	0·25	0·10	0·15
9.	0·33	0·14	0·19

It will be seen, from the tests of the first three samples, which were made in duplicate, that very concordant results are found by this process, and also that, in all the samples, the loss of weight due to the oil is very considerable as compared with the loss from other causes. In some instances this loss due to oil is about twice as much as the loss from oxidation and volatilisation.

The amount of loss from oxidation and volatilisation in all these samples is but small, varying from 0·15 to 0·28 per cent., and it may seem at first sight to be of little importance, but, actually, the correction of the assay corresponding to these small losses makes a difference on a lead containing, say, 500 oz. of silver per ton, of $\frac{3}{4}$ oz. of silver per ton in the first case, and 1 oz. 8 dwt. per ton in the latter case; and these amounts when deducted from the assays of the cakes of lead give the true contents of silver in the original lead. With richer leads the correction is, of course, proportionately greater.

It is obvious that in the above cases, if the correction for loss on melting the sawings were to include also the loss due to the oil, an error would be made which would lead to an *excessive deduction* varying from $\frac{1}{2}$ oz. to 2 oz. 12 dwt. of silver per ton, supposing the lead to contain 500 oz. of silver per ton by assay of the cake of melted sawings.

DISCUSSION.

Mr. SHAW suggested that liquation and separation of constituents might take place in the small ingot, but Mr. PATTINSON considered that it was too small and cooled too quickly for that to occur to any measurable extent.

Mr. RENNOLDSON thought that if the oil were first removed, its amount need not be determined; he also suggested the use of water as a lubricant in place of oil.

THE VARIATION IN THE COMPOSITION OF CAUSTIC SODA WITHIN THE SAME DRUM.

BY JOHN WATSON, F.I.C.

So far as I am aware, very few results have been published with a view to elucidate this important question.

At the suggestion of our worthy Chairman, I have pleasure in submitting the tests of several samples, taken from different parts of drums which we have opened, at various times, during the past four years.

First, it may be interesting to consider, briefly, what has already been published on this subject.

In the Chemical News, for 25th April 1873, a paper by Messrs. Glendinning and Edger, of this town, is to be found, "On the separation of caustic soda into portions of different strengths on passing from the fused to the solid condition."

These gentlemen state that when caustic soda, containing water in excess of that combined as hydrate, passes from the fused to the solid state, it separates into portions of different strengths. In such a case, a sample taken from the drum after cooling may, according to circumstances, they say, differ from that taken ex pot during the packing operation by several per cents.

A drum of caustic soda, containing 66·8 per cent. soda (Na_2O) and about 6 per cent. water, in excess of the water of hydration, was cut through its centre, transversely to its longitudinal axis, and samples were taken:—A, from the outside, not extending more than 1 in. towards the centre; B, from a part about 5 in. nearer the centre; and C, from

the centre itself. The radius of the drum was 11 in. The results were:—

	A.	B.	C.
Soda (Na_2O).....	66.9	69.7	Per Cent. 61.6

The outside, or A sample, invariably agrees closely with the packing sample, according to Messrs. Glendinning and Edger. Analyses of the above samples showed that the differences were chiefly due to water; but in some measure to chlorides and sulphates, these impurities occurring in largest quantities in the centre.

The differences in strength, due to separation, will be influenced by circumstances, say these authors, such as the quantity of water present, the temperature at the time of packing, and the size of the drum.

Finally, Messrs. Glendinning and Edger explained the higher percentage of water in the centre by a theory, of the greater affinity for water possessed by the fluid than by the solid caustic, which, as Dr. Lunge, has remarked ("Treatise on Sulphuric Acid and Alkali, Vol. II., p. 622), is very questionable.

Mr. John Morrison, according to Dr. Lunge (*loc. cit.* p. 622), entirely denies the difference of quality within the same drum; the former never found more than 0.2 per cent. difference in testing any portion of a block.

First, I wish to make it clear that the tests I am about to submit to you are those of caustic soda containing no water (except that combined as sodium hydrate), whereas the drum examined by the gentlemen first referred to contained about 6 per cent.

With regard to the difference between samples ex pot and those taken ex drum. For nearly three years at Allhusen's works we took samples both ways, and found the tests to be almost identical. Thus, in the average of one month's work which I have by me, there was only a difference of 0.06 per cent. between the tests of the two sets of samples, those ex drum being the higher.

This difference during the month may be considered to represent our experience over the three years, and now we only take pot samples in cases where we have to make lower strengths of caustic—70 per cent., &c.

In taking the samples, the tests of which are given below, the drums were laid on their sides, opened, and the block of caustic split across lengthwise. Pieces were then cut out as follows:—

- (1.) From near the top, out of the second crust.
- (2.) From the sides of the drum.
- (3.) From the centre.
- (4.) From the bottom.

The annexed rough sketch shows the regions from which the samples were taken.

In high-strength caustic soda, 76 or 77 per cent., a cone of discoloured caustic is almost always found at the bottom of the cylindrical mass.

In 70 per cent. caustic, so far as I have seen, the discoloured particles are generally to be found in a spherical, or lenticular patch, near the centre of the drum.

77 PER CENT. CAUSTIC SODA.

Samples taken from various parts of two drums of Allhusen's 77 per cent. caustic:—

	E 21.	L 66.	Mean of two Drums.
Top of drum (second crust).....	76.85	77.18	Per Cent. 77.01
Sides of drum.....	76.95	77.08	77.01
Centre.....	76.55	76.61	76.58
Bottom (discoloured cone).....	76.90	76.97	76.93
Average of the four samples	76.81	76.96	76.88
Greatest difference between two portions.....	0.40	0.57	0.43

It will be seen, from the above tests, that in the first drum, marked E 21, the highest test, 76.95 per cent., was obtained with pieces chipped from the sides of the drum, whereas the caustic chipped from the centre of the drum tested lowest, viz. 76.55 per cent. The greatest difference in this drum, therefore, was 0.40 per cent. soda. The second drum, L 66, tested highest at the top (second crust), viz. 77.18 per cent. soda, and again, the lowest test was from the centre pieces, viz., 76.61 per cent. soda; in this case the greatest difference between the various portions of the drum was 0.57 per cent. I shall refer to the tests of this drum again, later on. Taking the mean of the tests from both drums, it will be seen that the caustic was strongest at the top and sides, viz., 77.01 per cent., and weakest at the centre, viz., 76.58 per cent.

With a view to finding out the cause of the difference in strength within the same drum, I weighed off a considerable quantity (40 grms.), of the sample from centre of the L 66 drum, also a similar quantity from the top of the drum; the two chief impurities were determined with the following results:—

	Centre.	Top (2nd Crust).
Sodium chloride.....	0.54	Per Cent. 0.55
Sodium sulphate.....	1.42	0.87
Available soda.....	76.61	77.18

The difference in the percentage of sulphate, 0.55, is equivalent to 0.40 per cent. Na_2O .

70 PER CENT. CAUSTIC SODA.

Samples taken from various parts of two drums of Allhusen's 70 per cent. caustic soda:—

	L 78.	L 83.	Mean of two Drums.
Top of drum (second crust)	70.54	70.05	70.29
Sides	70.25	69.53	69.89
Centre	70.91	70.23*	70.57
Bottom.....	70.38	69.49*	69.93
Average of the four samples ...	70.52	69.82	70.17
Greatest difference between two portions.....	0.66	0.74	0.68

* In the case of these two portions the solution was slightly milky in appearance, owing, doubtless, to a trace of lime, which was filtered off and washed before titration.

From the mean of the above results it will be seen that the samples from the sides of the drum are the lowest in strength, those from the centre being the highest.

In a third drum of 70 per cent. which I had opened, I found, on testing, the same order, viz., the portions from the sides of the drum were weakest, those from the centre strongest, and in this case I had also taken the precaution of filtering off a trace of lime which was present in the sample from the centre.

The results given above show that in L 78 the centre was the strongest sample, testing 70.91, the portions taken from the sides were weakest, testing only 70.25, the greatest difference being 0.66 per cent. soda. In L 83, again, the centre sample was the strongest, 70.23; the sample from the bottom was in this case slightly weaker than that from the sides, testing 69.49, the greatest difference being 0.74 per cent. soda.

Analyses of the samples from the centre and bottom of L 83 gave the following results:—

	Centre.	Bottom.
		Per Cent.
Sodium chloride	9.54	9.26
Sodium sulphate	0.65	1.39
Available soda	70.23	69.49

Again it will be seen that the sulphate is very much higher in the weaker portion. The difference in the percentage of sulphate, 0.94 is equal to 0.73 soda per cent., whereas the difference in the soda was shown to be 0.74 per cent.

In the case of the 77 per cent. drum, marked L 66, and that of the 70 per cent. drum, marked L 78, I tested at least two portions from each part of the drum, and with a view to prevent hasty conclusions or dogmatic statements, I give the individual tests, which it will be seen show that there may be considerable variation within the same region of the same drum, e.g., in the centre of L 66, one portion tested 76.29, whereas other two portions tested 76.71 and 76.83 per cent.; again, at the sides of L 78, the first portion tested gave 70.50, but the second only 70.01 per cent.

Individual tests from various parts of a 77 per cent. and of a 70 per cent. drum:—

	L 66.	L 78.
		Per Cent.
Top (second crust) I.	77.22	70.56
II.	77.14	70.52
Mean	77.18	70.54
Sides I.	76.98	70.50
II.	77.19	70.01
Mean	77.08	70.25
Centre I.	76.71	70.86
II.	76.29	70.97
III.	76.83	..
Average	76.61	70.91
Bottom I.	77.00	70.44
II.	76.95	70.33
III.	76.97	70.38

To sum up, in conclusion, my experience, based on the examination of samples from various parts of seven drums, from different batches of caustic soda, goes to show that

the variation in strength is nothing like so great as was found in the isolated case reported by Messrs. Glendinning and Edger; but the different conditions as to moisture must be borne in mind. On the other hand, the greatest differences in strength between portions from the same drum, are, as a rule, according to my experience, greater than stated by our friend Mr. John Morrison. In the seven drums which I have examined, in only one case did I find the greatest difference as low as 0.20 per cent., in another case I found it as high as 1.34 per cent.; but the average of the seven drums gave 0.71 per cent. difference between the highest and the lowest tests. It is only fair to my employers to say that these seven drums of caustic included one not made at Gateshead.

It is notable that the lower the strength of caustic, or in other words, the greater the proportion of salt present, as a rule, the greater is the variation of strength.

THE USE OF FULLER'S SPIRAL SLIDE-RULE FOR CHEMICAL CALCULATIONS.

BY JOHN WATSON, F.I.C.

THE use of the slide-rule to facilitate calculations has been long known to chemists and engineers. In the transactions of the Newcastle Chemical Society, the Society which most of us regard as the parent of this Section, an interesting paper, by Mr. H. R. Procter, is to be found (Vol. IV. p. 330) on the use of the slide-rule for chemical calculations.

The ordinary slide-rule answers well enough for certain purposes, but to give a result of even three figures, where the third figure shall be strictly accurate, a rule is required of such length that its working becomes unhandy.

When we are reminded that this spiral slide-rule, which can be handled with ease, is equivalent to a straight slide-rule 83 ft. 4 in. long, or a circular rule 13 ft. 3 in. in diameter, we realise the advantage of this form which has been patented by Professor Fuller. Since 1879 this slide-rule has been obtainable from Mr. W. F. Stanley, the well-known instrument maker in Holborn.

In the preface to the first edition of "The Alkali Makers' Pocket-Book," by Drs. Lunge and Hurter, reference is made to the fact that the latter-named gentleman, in re-calculating the tables for English weights and measures, used Fuller's calculator and Thomas's arithmometer, to avoid errors of computation as much as possible. The use of this spiral slide-rule for chemical calculations, therefore, is not new, as the book referred to was published in 1884; but I venture to believe that there are many chemists in this district who have never seen a Fuller's calculator, and that is my excuse for taking up a little of your time in bringing so useful an instrument before your notice this evening.

It is due to my old friend, Mr. Walton Brown, of the Coal Trade Office, to say that he first showed me an instrument, similar to this, which he had used for some time.

Seeing that the calculator was likely to save much time, paper, and pencil, to say nothing of brain work, I obtained this instrument through Mr. Winter, in Grey Street, and we have had it in daily use for the last 18 months. During this period it has not required any repairs or re-adjustment, and is still as good as new. The price of an instrument such as this, in mahogany case, is 3*l*. A smaller rule, with a scale 200 in. long, giving an approximation of $\frac{3000}{30000}$ th, was made for some time and sold at 20*s*., but in November 1890 I heard from Mr. Stanley that the shorter rule was very unsatisfactory, and he had ceased making them. A pamphlet of 11 pages, giving instructions for the use of the rule, is presented with each instrument; it is therefore needless for me to give more than a brief description (partly taken from the pamphlet) of the mode of working.

The rule consists of a cylinder or muff, *d*, which can be moved up and down upon and turned round the axis *g*; the latter is held by the handle *e*. Upon the cylinder *d* a single logarithmic scale is wound in a spiral, the numbered

graduations being from 100 to 1,000. Each of the primary divisions up to 650 is divided into 10 parts, and from thence to 1,000 into five parts. It follows, therefore, that each number of four figures has either a mark upon the scale, or

(if above 650) is midway between two marks. Fixed to the handle is an index or pointer F, and fixed to the innermost cylinder *h*, which telescopes into *g*, are two indices, the upper J and lower K, whose distance apart is the axial length of the complete spiral. These moveable indices may be placed in any position relative to the muff *d*.

In using the slide-rule it will be found most convenient to hold the handle in the left hand, leaving the right hand to move the cylinder *h* by the top, and to note down with pen or pencil the results obtained. On the axial cylinder *g* several useful tables are printed; among others, one giving inches and vulgar fractions of inches as decimals of a foot, one for pounds and quarters as fractions of a hundred-weight, &c.

For a *simple multiplication* of, say, a number of four figures by another number of three or four figures—

Bring 100 to F (by use of catch).

Set K to the higher number.

Bring the lower number to F.

Read product at J or K.

For working such a case as—

$$\frac{a \times b \times c}{d \times e}$$

Professor Fuller informs me that he finds it more convenient to do without the stops; they can be easily removed if not required.

In the case of *division* of a number of two to five figures by a divisor of two to five figures—

Bring the divisor to F.

Set J or K to the number to be divided.

Bring 100 to F by use of the catch.

Read quotient at J or K.

Proportion, or "rule of three," is a combination of multiplication and division, and questions in this rule can be easily solved by use of the calculator. The instrument has other applications, for particulars of which I must refer those interested to the pamphlet to be had at Mr. Stanley's address.

As examples, I will give a few specimens of the kinds of calculation which a chemist would find this slide-rule useful for:—

Multiplication.—A precipitate of barium sulphate has been found to weigh 0.178 grm.; the factor for sodium sulphate is 0.6094, the product is obtained by the calculator in a very short time, strictly accurate to the *fourth* decimal figure; indeed, where required, a very close approximation can, in this case, be obtained of the fifth decimal figure. Working this example by pencil and paper, in the old way, in addition to the two factors, 14 figures would be written down before the product could be got by addition; but the time and trouble of writing these 14 figures is entirely dispensed with by using the calculator.

Division.—A sample lump of caustic soda weighing 5.565 grms. is dissolved in water and titrated by standard acid (1 cc. = 0.100 grm.), 42.85 cc. being required:— $42.85 \div 5.565$ gives the percentage of soda in the sample. The quotient, to the second decimal place, can be obtained in a very much shorter time by the calculator than by working out on paper, and, by use of the instrument, the writing down of some 29 figures is obviated.

Proportion.—Numerous examples might be given; but, if time is saved by the use of the calculator in multiplication, and also in division, *a fortiori*, in the combination of the two, time is also saved.

One case where the calculator will be found to save much time, is in that class of analyses where the constituents have been determined, say, in the wet state, and are to be calculated to the dry state. In an actual case a sample had the following constituents:—

In Original State.	Calculated to Dry State.
48.81	55.86
25.25	28.90
7.55	8.64
0.77	0.88
0.74	0.85
4.10	4.69
Moisture 12.60	..
99.82	99.82

In calculating the first item in the above analysis to the dry state, the proportion would be stated—

$$87.22 : 99.82 :: 48.81 : x$$

We find by the calculator the quotient got by dividing the first term into the second, viz., 1.1445, and leave the moveable pointer K at that quotient. Now bring round the muff or cylinder *d* till the third term of the proportion is opposite the fixed pointer F. The answer is read at the moveable pointer. To get the second item, in the dry state, simply move the muff till the graduation, 25.25, is opposite the fixed pointer and again read the answer at the moveable pointer; and so on through the analysis, it being only necessary to move the muff to bring the graduation of each fresh number opposite the fixed pointer.

I need scarcely say the description of the method of working takes up a much longer time than the actual working of the instrument itself does.

Another instance, which should come under the heading of multiplication, may be given:—Some 18 months ago, we had to determine the areas of a large number of liquor tanks and settlers; having measured the length and width, we found the calculator (with its table giving decimals of a foot) very useful for working out the areas.

Some may possibly say "You are comparing the instrument with old-fashioned methods of working chemical calculations. Why not use logarithms?" I must confess, frankly, that I was never enamoured with the use of logarithms; but, as I have tried them at two or three different periods, I am not biassed against their use. Recently, I worked a set of calculations with this calculator, against a chemist who regularly uses logarithms, he using his "logs." The result of the contest was decidedly in favour of Professor Fuller, both as to speed and accuracy.

Mr. HUGH BARCLAY made a verbal communication on a process for the ready and accurate determination of the loss of coal in coal-washing operations. He also gave a demonstration of the process, which depends on the separation of constituents of different densities by a liquid of intermediate density.

SESSION 1892.

1892:—

May.—Mr. C. Spackman, "Notes on the Manufacture of Portland Cement from Lime Mud after Treatment by the Chance Sulphur Recovery Process."

Meeting held Thursday, February 10th, 1892.

MR. L. ARCHBUTT IN THE CHAIR.

ON AN IMPROVED FORM OF PIPECLAY TRIANGLE.

BY J. B. COLEMAN, A.R.C.S.C., F.I.C.

In the various supports used for holding crucibles and like vessels during heating, the following disadvantages are present:—

1. Platinum triangles on heating to a high temperature expand and soften, inducing "sagging." If platinum vessels are heated, partial fusion between the wire and vessel may occur. The expense also is considerable, and effectually precludes its use by all but advanced students.

2. The ordinary pipeclay triangle prevents contact of the flame, except at the three angles, particularly if the vessel to be heated is small, such as crucibles, &c.

3. Triangles made entirely of porcelain and fireclay are fragile and expensive.

The modification in the improved form of triangle shown in Fig. 1 consists simply in making a flange in the middle

Fig. 1.

portion of each of the three pieces of pipeclay forming the triangle. In this way contact takes place in three points

only, and thus leaves ample space for the flame to play upon the surface exposed. The result is that thorough contact between the flame and the vessel to be heated is secured. The effect of this improvement is to lessen the time of heating, and also to increase the temperature attainable from a given flame.

The following experiments show the advantages of the triangles. The flame used in these experiments was that from a Bunsen burner, the gas supply of which was regulated by means of a Stott's governor.

1. A platinum crucible was used and 10 cc. of water were gently heated to boiling, first in the improved and then on the ordinary form of triangle; the time required was carefully noted. Results:—

	Temp. of water, 21° 3' C.	Temp. of air (constant), 13° C.	Seconds.
Improved triangle.	Time required for 10 cc. of water.		45
Ordinary " "	" " " "		60
Difference in favour of improved triangle			15

2. (a.) A platinum dish was employed, 50 cc. of water were heated to boiling on both forms of triangle, and the time required noted. Results:—

Seconds.	
Improved triangle with 100 cc. water	65
Ordinary " " "	85
<hr/>	
Difference in favour of improved triangle.....	20

(b.) Into a porcelain dish 2½ in. diameter, 103 grms. of an alloy of lead and tin were introduced. The dish was heated until the alloy was thoroughly melted and the time required noted:—

	Min. Secs.
With improved triangle	2 20
„ ordinary „	2 50
<hr/>	
Difference in favour of improved triangle.....	30

Hence the gain in time was from 20 to 25 per cent.

3. In flat-bottomed vessels the results were not so good, but were slightly in favour of the improved form of triangle.

4. Experiments were also made in burning off organic matter. In some cases the time occupied was less than half that required when the ordinary form of triangle was employed.

To sum up, the triangle is cheap since it can be made in long lengths and cut up into suitable portions by means of a file, which are then threaded and bound together by iron wire in the ordinary way. It is strong, since the flange is made at the weakest point, that is, at the middle. It is economical, since a higher temperature and more rapid heating is obtained from a given flame.

In the experiments recorded above, ordinary pipeclay was used. The mould was made of hard wood, a smooth iron wire being used for the core. After the clay was moulded into shape the wire was withdrawn, and the clay dried in the steam oven, and finally heated for several hours in a muffle furnace and allowed to cool slowly. For use on a large scale polished steel moulds will be found suitable so as to admit of a greater length of pipeclay being made at once, which may after annealing be cut up into the required lengths.

DISCUSSION.

The CHAIRMAN exhibited a welded platinum triangle which he had used for many years. He found it an advantage to be able to alter the shape of the triangle to suit different sized crucibles. There was always a slight adhesion between the triangle and the crucible at a red heat, but even after heating in the blowpipe flame no transference of metal took place. It was, however, advisable to allow the triangle and crucible to cool down below redness before separating them; a slight touch was then sufficient. Mr. Coleman's triangle was a great improvement on the ordinary clay triangle.

A CONVENIENT FORM OF DISTILLATION FLASK FOR THE ESTIMATION OF AMMONIA IN WATERS, AND FOR OBTAINING WATER FREE FROM ORGANIC MATTER.

BY J. B. COLEMAN, A.R.C.S.C., F.I.C.

IN the estimation of "free" and "albuminoid" ammonia in water considerable difficulty in freeing the apparatus from ammonia gas is experienced. This is not so great if a retort be used as the distillator. But even in this case, in the adaptation of the neck of the retort it is necessary that the steam comes into contact with rubber-joints, unless the retort is small; since, if large retorts are used, it is necessary to draw out the neck so as to fit into the inner condenser tube, or a specially large condenser tube must be used. The apparatus then is somewhat cumbersome.

If a corked flask be used in place of a retort, the steam comes into direct contact with the cork, and with the majority of corks the supply of ammonia appear exhaustless. Analysts well know the value of a cork which is not a source of ammonia in the above operations.

By employing a distillation flask into the neck of which is fused a side tube fitted with a light, hollow, glass stopper, all the above objections are done away with. The stopper, when wetted, is perfectly steam-proof, even if the grinding is indifferent. The side tube passes several inches down the inner condenser tube, which is of just sufficient diameter to admit it, and so the rubber-joint is obviated, perfect condensation occurring without escape of steam.

The water or reagent may be added without disturbing the apparatus by simply taking out and replacing the stopper.

It will be seen that by employing large flasks, water free from organic matter can be conveniently prepared in this apparatus.

A SIMPLE METHOD OF CALIBRATING A DELIVERING PIPETTE.

BY PROFESSOR FRANK CLOWES, D.S.C., F.I.C.

The following will be found to be a simple and accurate way of estimating the capacity of a pipette, no stop cocks or other additional apparatus being needed.

The clean and dry pipette is first provided with an arrangement for closing the delivering end so that it may be weighed while it contains water.

This arrangement is effected by slipping a strip of rubber 4 in. long and $\frac{1}{2}$ in. wide over the lower end of the pipette, then drawing up the free ends on opposite sides under slight tension and binding them tightly with copper wire. The rubber now forms an elastic loop, with which the end of the pipette may be closed at pleasure. An india-rubber ring cut across answers admirably for this strip.

In the process of calibration the rubber loop is drawn aside and the pipette filled by suction. The pipette is allowed to empty and drain for half a minute, and the end being at once closed by the rubber band, is weighed at once. Distilled water at 15.5° C. is now introduced into the upper end of the pipette by means of a fine wash-bottle jet, until the graduation is reached. The pipette is now weighed again. The increase in weight should be equal to the weight of the registered number of cc. at 15.5° C. Should this not be so, a little water may be added or taken away by means of a piece of glass tube drawn out into a slender capillary.

Having adjusted the weight of water so as to correspond with the registered volume, the graduation is then made in the usual manner.

Professor Clowes also showed and described his apparatus for testing the sensitiveness of different forms of miners' safety-lamps when employed for detecting low percentages of inflammable gases in the air.

Meeting held Thursday, March 31st, 1892.

ON DUMAS' METHOD OF ESTIMATING NITROGEN IN ORGANIC BODIES.

BY JAMES O'SULLIVAN, F.I.C., F.C.S.

OF the methods employed to determine the quantity of nitrogen in organic compounds there is not one more favoured, and justly, than that of the absolute method of Dumas. This process entails more labour, and takes more time than any other, but this is compensated for by the faith which can be placed in the results obtained by it.

Dr. Frankland (Phil. Trans. vol. cxlvii. p. 59) in his classical researches "On the Substitution of Nitrogen for Carbon in Organic Compounds," experienced considerable difficulty in estimating the nitrogen in the substitution products. He employed Simpson's modification of Dumas' method and found it impossible to obtain the resulting gas free from considerable quantities of nitric oxide, although the gas was made to stream over 12 inches of copper. To obtain the absolute volumes of nitrogen and nitric oxide, a gas analysis apparatus had to be employed.

My experience with the absolute method proves that the gas obtained invariably contains an appreciable quantity of nitric oxide, and that the amount is not much influenced by the presence of the usual copper in the combustion tube.

The estimations of nitrogen in the undermentioned substances, except where it is otherwise stated, were not made to prove this, but were simply parts of an analytical process.

The combustion tube was filled as in Dumas' method; however, the bicarbonate of soda was dispensed with, as a Sprengel pump was in all cases employed to obtain a vacuum and to collect the resulting gases when the combustion was completed.

The copper oxide employed was prepared from copper wire cut in lengths of about 5 mm., and the copper was a roll of copper gauze 3 in. long, enclosed in a piece of sheet copper; this was oxidised and reduced by hydrogen prior to use.

The time taken to burn the extracts mentioned was in no case less than three hours, and the remaining bodies tabulated, being more difficult to burn, took about four hours. Arsenious acid mixed with the copper oxide, as advised by Strecker, did not have any influence in accelerating the combustion. A gas-analysis apparatus was employed in all cases to determine the absolute volumes of nitrogen and nitric oxide in the resulting gas which was collected over potash. The total volume of gas was first determined, and after the addition of an excess of oxygen in the presence of potash, the excess of oxygen was removed by a few drops of pyrogallin. The residual gas, being nitrogen, was then determined, and the difference between this quantity and that of the original gas gave the nitric oxide present, which was absorbed as nitric peroxide by the potash.

In Table I. is shown the maximum, minimum, and average percentages of nitric oxide in the resulting gas when copper was used in the combustion tube:—

TABLE I.

Number of Determinations.	Substance.	Percentage of Nitric Oxide on Total Gas.		
		Maximum.	Minimum.	Average.
6	Barley.....	9.81	3.56	7.38
3	Malt.....	11.70	4.37	8.20
2	Alcoholic extract of barley	8.00	2.73	5.11
5	Alcoholic extract of malt...	5.72	2.81	4.38
4	Insoluble residue of barley (grains).	4.20	2.62	3.06
5	Insoluble residue of malt (grains).	9.96	3.06	6.42

These numbers, to which many more obtained from similar bodies could be added, show that with all the substances burned, even though there was copper in the combustion tube, nitric oxide was present in the gas.

I have had considerable experience with Dr. Frankland's method of determining organic carbon and nitrogen in water residues and have never obtained a gas that did not contain nitric oxide although copper was always used.

It occurred to me, as my experience proved the invariable presence of nitric oxide in the gas, which had to be estimated, in all cases, that the copper might be discarded and a plug of asbestos substituted. This does away with the tedious process of preparing, by reducing with hydrogen, the oxidised copper, and it will be seen from Table II. that not much more nitric oxide is found in the gas thus obtained.

TABLE II.

Number of Determinations.	Substances.	Percentage of Nitric Oxide on Total Gas.		
		Maxi- mum.	Mini- mum.	Aver- age.
12	Beer.....	7.12	3.00	5.38
6	Barley.....	10.08	7.83	8.85
8	Malt.....	13.70	5.82	8.72
5	Alcoholic extract of barley.	14.90	7.00	9.95
10	Alcoholic extract of malt...	8.37	3.64	5.84
1	Insoluble residue of barley (grains).	4.20	2.62	3.06
8	Insoluble residue of malt (grains).	12.00	3.00	9.30

In order to show that the nitric oxide was not due to the substances being burned under a reduced pressure, as is the case when a Sprengel pump was used, I made a few determinations by breaking the vacuum before proceeding with the combustion of the substance. A longer combustion tube than usual was employed. About 0.3 grm. of cane sugar was placed at the closed end of the tube, which was then filled with the copper oxide and the substance, after which a much larger quantity of copper oxide was placed than usual. When the vacuum was formed, three to four inches of the front of the tube were heated to redness and then the end containing the cane sugar. As soon as the vacuum was broken by the carbonic anhydride the combustion was proceeded with in the usual manner. Four determinations of nitrogen in malt were made in this way, two without copper in the tube, one with copper, and one with a coil of silver foil instead of copper. The resulting gases contained the following percentages of nitric oxide on the total gas measured:—

	Per Cent.
No. 1, without copper.....	8.14
No. 2, ".....	9.55
No. 3, with copper.....	9.00
No. 4, with silver.....	8.49

Two determinations of nitrogen in uric acid were made without employing copper; in one the vacuum was broken by cane sugar and the following are the numbers obtained:—

	N.O. ₂ on Total Gas.	Nitrogen.	Theory.
	Per Cent.	Per Cent.	Per Cent.
No. 1, vacuum broken.....	5.15	Found 33.8	33.3
No. 2, " unbroken..	4.80	" 33.4	

I have observed that in the determinations of carbon and hydrogen in bodies containing nitrogen, especially when the substances were burned in oxygen, that the water in the

chloride of calcium tube tasted acid and had an acid reaction whether copper or silver was used in the combustion tube. This shows the presence of nitric peroxide in the gas which must be absorbed by the potash bulbs, and consequently increases the carbon number. Dr. Frankland, in the work already mentioned, observed that his carbon results were high, and ascribed this to the formation of potassic nitrite. (Frankland's Experimental Researches, 232.)

The quantities of the substances burned are not given here, nor the amounts of the gases obtained; however, the total gas measured in any case was not more than 0.04 grm., and not less than 0.008 grm.

In conclusion, my experience of the determination of nitrogen by this process shows that copper can be dispensed with, and as there is always nitric oxide in the gas the most accurate results are obtained by measuring the quantity of nitric oxide and nitrogen in the gas by means of a gas-analysis apparatus.

THE VOLUMETRIC DETERMINATION OF CALCIUM PHOSPHATE BY MEANS OF URANIUM SOLUTION.

BY J. B. COLEMAN, A.R.C.S.C., F.I.C., AND J. D. GRANGER.

In the volumetric estimation of calcium phosphate by means of uranium solution, it is stated by some authorities that to obtain correct results calcium phosphate in place of sodium phosphate must be used for standardisation.

To ascertain the relative accuracy of the two methods the same uranium solution was standardised, firstly, by means of sodium hydrogen phosphate solution, and secondly by means of calcium phosphate solution.

The method employed in all the determinations was the following: A solution of uranium nitrate, previously mixed with sodium acetate, was run into an acetic acid solution of the phosphate, also previously mixed with sodium acetate. The titration was performed at 80° C.

The end of the process was indicated when a drop of the liquid gave a faint brown colouration with a drop of potassium ferrocyanide.

It should be noted that an appreciable quantity of free acetic acid retards the formation of the colour considerably, therefore as little free acid as possible was used.

The sodium phosphate, $\text{Na}_2\text{HPO}_4 \cdot 12 \text{H}_2\text{O}$, used was twice crystallised and dried between filter-paper. It was analysed and found to contain 19.60 per cent. of P_2O_5 against 19.83 per cent. by theory, this difference being probably due to the presence of a little moisture.

The pure calcium phosphate was prepared by the addition of a solution of Na_2HPO_4 to an alkaline solution of CaCl_2 , the latter being kept in excess. The precipitate was washed and finally dried in the steam oven. It is stated that this precipitate varies in composition. Three samples were prepared by the above method. The P_2O_5 precipitated with ammonium molybdate and the precipitate dissolved in ammonia, and re-precipitated by means of magnesia mixture and weighed as $\text{Mg}_2\text{P}_2\text{O}_7$.

The percentage of P_2O_5 in the specimens were 46.93, 48.86, 49.59, whereas $\text{Ca}_3(\text{PO}_4)_2$ contains 45.82.

Since these numbers varied greatly, another sample of calcium phosphate was prepared by adding an alkaline solution of Na_2HPO_4 to a solution of CaCl_2 . This sample was analysed by the method mentioned above and found to contain 45.18 per cent. P_2O_5 .

A standard solution of calcium phosphate was next prepared, containing 2 grms. of P_2O_5 per litre, i.e. 50 cc. = 0.1 grm. P_2O_5 .

For this purpose 2.0164 grms. of calcium phosphate containing 49.59 per cent. of P_2O_5 were dissolved in a little nitric acid; the acid was then neutralised by ammonium hydrate and a slight excess of acetic acid added. The solution was then made up to 500 cc.

The standard solution of $Na_2HPO_4 \cdot 12 H_2O$ was made up by dissolving 10.203 grms. of the sodium phosphate containing 19.60 per cent. of P_2O_5 in water and making up to a litre; this solution therefore contained 2 grms. P_2O_5 per litre, and was therefore the same strength as the calcium phosphate solution.

A solution of uranium nitrate containing 35 grms. per litre was prepared and run from a burette into separate 50 cc. of the above solutions, in the manner described, with the following results:—

50 cc. of the calcium phosphate solution required 19.80 cc. of uranium solution.

50 cc. of the sodium phosphate solution required 20.85 cc. of uranium solution.

Thus the uranium solution, if standardised by sodium phosphate, would give too low results when used for estimating calcium phosphates.

Thus if the calcium phosphate contained—

50 per cent. of P_2O_5 the error would be 2.51 per cent.

10 per cent. of P_2O_5 the error would be 0.50 per cent.

The uranium solution (standardised by means of calcium phosphate) was then contrasted against the gravimetric process for estimating phosphates. For this purpose analyses were made with samples of calcium phosphate, first by precipitating by ammonium molybdate, and finally estimating as $Mg_2P_2O_7$ and also by titration with uranium solution.

The following results were obtained with two samples of calcium phosphate:—

Percentage of P_2O_5 found.	Calcium Phosphate (1).	Calcium Phosphate (2).
Uranium method	47.16	45.16
Gravimetric estimation	46.93	45.18
Difference	0.23	0.02

The above results show that to obtain correct results in volumetric determination of calcium phosphate, by means of uranium solution, (1) the uranium solution must be standardised by means of calcium phosphate; (2) the percentage of P_2O_5 in the calcium phosphate used for standardisation must be estimated gravimetrically.

Also, sodium phosphate cannot be used for standardisation as the results will be low, especially if the proportion of calcium phosphate is considerable.

MR. GEORGE WARD IN THE CHAIR.

NOTE ON THE TECHNICAL ANALYSIS OF GAMBIER, &c.—No. 2.

BY H. R. PROCTER, F.R.C.

Lecturer on Leather Industries, Yorkshire College, Leeds.

At the time of writing the Preliminary Note on the Analysis of Gambier, which appeared in the Journal of Aug. 1891 (681), it was anticipated that at an early date a report might be made recommending a method for general adoption. This has not proved possible for various reasons. In the first place, a communication has been received from Director Eitner, of the Vienna *Versuchsstation für Lederindustrie*, in which he declines for the present to take part in the establishment of any standard method, on the ground that he is dissatisfied with all those at present in use, and that he hopes before the close of the year to complete investigations which will give a new basis for such estimations. Having regard to the previous contributions of the Vienna Station to the technology of leather manufacture, and to its wide influence among leather chemists, it is clear that it is of no use to attempt to anticipate the publication of Director Eitner's results by any convention based on present methods. Another reason for delay is that lack of time, and the complications of the problems involved, has prevented the writer from giving the investigation which they demand to several points named in his previous communication. Some progress has, however, been made, and it seems worth while briefly to describe the methods now in use at the Yorkshire College, not as final or perfect, but as giving constant and reliable results without unreasonable expenditure of time.

The question of the estimation of catechin in gambier as apart from catechutannic acid, is reserved for further investigation; together with the equally important one whether it must be regarded by the tanner as a valuable or injurious constituent. It is undoubtedly the cause of a troublesome "disease" of leather known as "the whites." When gambier is dissolved hot, and added in large quantities to cold liquors, a portion of the dissolved catechin is generally precipitated in an amorphous form, as has been pointed out to me by Mr. Bertram Hunt; but under some imperfectly understood conditions, of which gradual cooling of the liquor in cold weather is possibly one, the supersaturated

solution deposits crystalline catechin, either in the interior, or on the surface of the hides, forming unsightly white blotches, which are only removed with some difficulty by handling in warm liquors. The nature of the defect has been recently investigated in the Leather Industries Laboratory of this College, and it has been found that the appearance of the white matter is distinctly crystalline under the microscope, and that when portions are scraped off and dissolved in hot water, and allowed to crystallise on a micro-scope slide, the crystals formed are identical in their appearance and reactions with those obtained direct from gambier. Some gambiers are much more apt to produce this defect than others, probably from their higher percentage of catechin, and as this substance is easily converted into uncrystallisable gambier-tannin by exposure to heat, it becomes a question of importance whether gambier would not be improved for use in tanning by such treatment. Cube-gambier, which contains the highest percentage of catechin, and which is hence most apt to cause "whites," would have its catechin converted completely into tannin by drying at a temperature of 120° C., say on the top of a steam boiler.

The following are the details of the method at present employed.

Sampling.—With regard to block-gambier, it has been found practicable to sample satisfactorily, either by cutting slices through the blocks, or by the use of a tubular sampling tool like a large cork borer, fitted with a wooden plug or plunger to force out the cylinders of gambier. It is desirable that this tool should be long enough to pass completely through the block, or in withdrawing it, a good part of the cylinder which is cut is apt to be expelled by the pressure of the air, which cannot find its way down the sides of the tool. Probably a common tin pea-shooter might be used successfully as a makeshift. In any case, the whole sample drawn from several blocks must be at once thoroughly kneaded up into a single homogeneous mass, and enclosed in a bottle or tight tin, to prevent loss of moisture. Such samples soon become mouldy on the outside, which might possibly be prevented by the use of a few drops of turpentine, or some other volatile germicide in the bottle, but the interior of the sample is only very slowly affected. The sampling of other tanning materials calls for no special remark, except that in preparing various hard fruits, such as valonia and myrabolams for grinding in small mills, the use of a heavy short-handled hammer, on a thick metal plate, surrounded on three sides with raised ledges to stop flying fragments, as proposed by Mr. A. Neubald Palmer, is very convenient.

Quantity of Material employed.—It was mentioned in the previous note that while at the Vienna Versuchsstation such a quantity of tanning material was employed as to give a solution containing 1.0–1.2 per cent. of dry extract, Professor von Schroeder and Dr. Koch used solutions containing only from 0.2–0.5 gm. per 100 cc.; and other chemists solutions of intermediate strength. At the Yorkshire College, solutions of 0.6–0.8 gm. of dry extract per 100 cc. are used. This medium strength has been chosen, not only as giving results not very divergent from either of the extremes, but as being practically more convenient than either, lessening, on the one hand, the objectionable evaporation required with many materials, to obtain the necessary concentration for the Vienna method, and the amount of hide-powder used, and on the other, the serious errors introduced by solubility of hide-powder, and small inaccuracies of weighing, in working with extremely small quantities of substance. It is argued by the advocates of stronger infusions that only liquors of such strength as can be practically employed in tanning should be used; the strength of 0.6–0.8 per cent. can scarcely be objected to on this ground, since in 256, 100, of the *Gerber*, the organ of the Vienna Versuchsstation, the strengths of 18 Austrian handler-liquors are given which all range below 0.6 per cent., and equally weak liquors are used for certain purposes in this country. Conversely, it is pointed out by Von Schroeder, that certain tanning colouring matters are only soluble in much water, and that chemists should endeavour to estimate the whole tanning substance present.

To this it may be replied, that with many materials no practical amount of water will keep the whole of these bodies in solution; and that there is no need to estimate more than will dissolve in liquors of practical strength, as a large percentage is generally rather injurious than beneficial to the tanner on account of their dark colour.

In order to obtain infusions of the strength named, approximate quantities for the following materials are given below:—

	Per litre.
Cutch, cube, gambier, and dry extracts, algarobilla, galls.....	8 grms.
Block gambier, divi-divi, valonia, myrabolams, mimosa.....	10 "
Sumach, canaigre, liquid extracts, mangrove bark.....	15 "
Angica bark, Persa bark, "Gambia" pods.....	20 "
Babool bark, quebracho wood, cork bark.....	30 "
Oak, hemlock, and larch bark.....	40–50 "

Preparation of Infusion.—**Extracts.**—The weighed quantity is dissolved in nearly boiling water, made up to about 1 litre, and cooled rapidly under the tap, the neck of the flask being covered with a small beaker, as the stopper is apt to stick. When cooled to 15° C. it is made up exactly to the mark and at once filtered. At the suggestion of Dr. Robert Hellon, Schleicher and Schull's pleated hardened filters No. 588 of 1½ cm. diameter are used for this purpose, and generally give at once a clear filtrate. If not, the first portions must be rejected. As some chemists have stated that tannin is absorbed by paper, the first 100 cc. filtered is used for the hide filter. Gambier is treated in the same way, with the exception that water of about 80° C. is preferable to boiling, as it dissolves the tannin just as completely, but gives an infusion which filters more readily. The gambier is dissolved in a beaker with successive quantities of the water, settling and pouring off the solution from the undissolved part till it is practically colourless. Dr. Hellon uses a von Schroeder's extractor, which is very convenient if at hand, as the coarser particles cannot pass through the muslin on the piston until dissolved or reduced to a fine state of division, and the insoluble matters are left behind in a state very suitable for examination. The same end would be attained by filtration through muslin.

Solid materials such as barks, valonia, &c. are best exhausted in the extractor devised by Dr. Koch of Leipzig, or in the somewhat simpler modification used by the writer. In its original form this apparatus consists of a flask fitted with an india-rubber cork with two perforations. One of these carry a short glass tube which does not project into the flask, and which can be connected by means of rubber tube, with a supply of distilled water on a shelf 4 or 5 feet above it. Through the second hole passes a tube, long enough to reach the bottom of the flask, and slightly widened at the lower end, and covered with a piece of silk gauze such as is used for dressing flour. The upper end of the tube is connected with a short piece of rubber tube provided with a screw pinch-cock (the food regulators supplied by druggists for use on babies' bottles answer very well). In use, a layer of dry sand purified by hydrochloric acid of $\frac{3}{4}$ in. deep is put in the bottom of the flask, and the material to be extracted is introduced by means of a wide funnel; the filter tube is passed down through it into the sand, while at the same time water is drawn into the flask, by immersing the short rubber tube in a beaker, and sucking at the longer one, which is afterwards connected with the raised water-bottle while the infusion is allowed to drop slowly into an empty flask from the shorter tube. The cork is secured with string or a special clamp. The apparatus forms, in fact, a simplified Real's press, with the advantage that it can readily be placed in the water-bath for hot extraction. Its most serious disadvantage is that, the filtering area of the gauze being small, it is easily choked by finely-powdered materials, and is extremely difficult to clear without taking the apparatus to pieces. It is also a little troublesome to fill.

To avoid these difficulties the following modification has been devised by the writer, with very satisfactory results. As no particular advantage is gained by working under

pressure, an ordinary open beaker is used as the extracting vessel, a common thistle-head funnel is bent twice at right angles to form a syphon, and the head is covered with gauze. This is placed on the bottom of the beaker and held in position by an ordinary retort stand clamp. A layer of purified sand is poured in to the depth of half an inch or more, and then the tanning material for extraction, either dry or after digesting overnight in a flask or beaker with, say, 200 cc. of water. I purpose trying whether exhaustion of the air under an air-pump at this stage will not assist the water in penetrating the material. The outer arm of the funnel is now connected with about 30 in. of small rubber tube fitted with a pinch-cock, and the syphon is started by sucking, and allowed to drop slowly into a flask placed below to receive it. If it be desired to extract at any temperature above that of the laboratory, the beaker is placed in a water-bath which is large enough also to contain a flask of water which is used to refill the extractor as it becomes emptied. In case it is found that one litre of water is not sufficient fully to exhaust the material, it is generally best, after about 800 cc. has been passed, to change the receiving flask, and continue the exhaustion till complete, afterwards concentrating the later washings by boiling in a flask with a funnel in the neck, until they can be added to the first 800 cc. In this way only the last remnants of tanning matter are exposed to the possible injury of evaporation. It is sometimes of interest, especially when the extraction is made first at a low temperature and then at a higher, to keep the two extracts separate, and after concentrating the last sufficiently, to make a separate determination of its tanning matter.

It has been shown by Messrs. Seymour-Jones and A. N. Palmer, that many if not all materials will yield a larger amount of tannin at lower temperatures than if extracted throughout at a boiling temperature, and the whole question of temperature in extraction is one which will evidently pay for investigation.

Removal of Matter absorbable by Hide.—After careful comparison between the various digestion methods, and the use of the hide-powder filter, I have come to the conclusion that the latter is not only the most rapid and convenient, but gives the most accurate and constant results, and the most complete absorption of any method which has yet been proposed. In this investigation I have been rather prejudiced against than in favour of the filter method by the fact that it was my own invention. In comparing it with various methods of digestion and percolation, I have noticed that the figures given by the filter were a limit towards which the other processes tended the more nearly the more completely they were carried out, but which they never passed. In all cases which I have compared, the hide-powder filter tends to more complete absorption, and consequently higher results in "tanning substances." The greatest difficulty in the use of the filter in the form given it by the Vienna research station, is that, in spite of the upward filtration, the infusion has a great tendency to pass up the sides of the glass rather than through the hide-powder, so that the inner part of the powder is practically inoperative. This difficulty is largely overcome by the form at present in use at the Yorkshire College, in which, instead of a cylindrical tube about 1 in. diameter and 4 in. long, and holding about 9 grms. hide-powder, the upper part of an ounce bottle is employed, forming a bell-shaped vessel about as wide as it is high, and holding only about 6 gm. of the lightly-packed hide-powder. The syphon tube, of about 9 in. in the longer limb, is allowed to project about $\frac{1}{2}$ in. through the cork, and is plugged with a small tuft of cotton wool, while the powder is retained in position by a piece of muslin held by an elastic band. The general arrangement is very similar to that of the syphon extractor above described, the filter being placed in a tumbler and the liquor added gradually, allowing it to wet the powder by capillarity. This is easily done in less than an hour, when the syphon is started by sucking, and drops very freely. The first 30 cc., which contain most of the soluble matter of the hide, are rejected, and the next 50 cc. used for evaporation to give the "soluble matter not tanning."

Evaporation and Drying.—Portions of 50 cc. each of the infusion before and after passing through the hide-powder filter are evaporated to dryness on the water-bath, and are then dried for 10 minutes in an air-bath at 110° C., cooled in the desiccator and weighed, and again dried for 10 minutes, when the weight will usually be found constant. Long drying is not advisable, as the residues gain in weight through oxidation. Three-inch porcelain basins are generally used.

Water is determined on a separate portion of the original material by drying at 110° C. In the case of block-gambier and liquid extracts, the quantity used should not much exceed 1 gm., and should be spread over the sides of the crucible to expose as much surface as possible, or the drying will be very slow. The temperature chosen has been found to admit of rapid work without danger of decomposition of the tannins. Any catechin present loses its first molecule of water of combination and is converted into catechutannic acid. This also takes place at 100° C., but with such extreme slowness as to render any determination very tedious.

Ash.—It is generally advisable to determine the ash as a check on adulteration and means of distinguishing the character of certain extracts; but it cannot be added into the analysis, as it is partly present in the soluble and partly in the insoluble residues, and its separate determination involves an amount of trouble which is hardly justified by the result.

Calculation.—The amount of extract after hide filtration deducted from the "total soluble extract" gives the "tanning matter absorbed by hide" (which of course includes colouring and other matters which are not strictly tannins). The "total soluble extract" deducted from the dry substance found in the water determination, gives the "matter insoluble in cold water." The extraction and determination of "tannin matter" are of course always done in duplicate, and give results generally differing only by the fraction of 1 per cent. in materials where accurate sampling is possible. This may be illustrated by a series of "oakwood" extracts taken as they occur in the laboratory book without selection.

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies and will take office in July next: Chairman: C. A. Fawsitt. Vice-Chairman: E. J. Mills. Hon. Secretary and Treasurer: J. Stanley Muir. Committee: G. Beilby, W. J. Chrystal, J. S. Macarthur, T. L. Patterson, E. C. C. Stanford, and G. Watson.

Meeting held in the Societies' Rooms, 207, Bath Street, Glasgow, on Tuesday, April 5th, 1892.

MR. E. C. C. STANFORD IN THE CHAIR.

THE "DRY HEAT" VULCANISATION OF RUBBER, WITH SPECIAL REFERENCE TO THE USE OF AN IMPROVED VULCANISER.

BY CHARLES A. FAWSITT, F.R.S.E., F.R.S.

For the vulcanisation, or as it is technically termed, the "curing" of rubber, four processes are in use, namely, the steam, dry heat, cold cure, and vapour processes.

The "steam" process is used almost exclusively for all goods termed "mechanicals;" and the goods to be cured are packed, either unprotected, or wholly or partially covered, into large iron vessels into which direct steam is turned until the pressure corresponding to the temperature necessary for the proper curing of the goods is reached, and is continued for a time, which varies according to quality, thickness, &c., of the goods. The "dry heat," "cold cure," and "vapour" processes, are principally used in the curing of waterproof cloth.

The "dry heat" consists in mixing the rubber with a small percentage of sulphur and other ingredients, and "curing" the cloth spread with such a mixture in a stove or air chamber heated by pipes or chambers through which steam or hot air circulates.

The "cold cure" process consists in exposing the rubber composition which has been spread on the cloth to the action of chloride of sulphur dissolved in bisulphide of carbon or other solvent.

The "vapour" process consists in exposing the goods which are to be cured to the action of the vapour of chloride of sulphur alone or mixed with nitric acid in large chambers, or merely by passing the proofed side of waterproof cloth over vessels in which the same reagent is slowly evaporated.

I shall, in what remains of this paper, treat almost exclusively of the curing of waterproof cloth, or, more correctly speaking, of the film of rubber which renders the cloth waterproof.

At present there is a revolution taking place in the rubber trade, so far as the vulcanisation of waterproof cloth

is concerned, in favour of the "dry heat" versus the "cold cure" process; and, considering the usual disinclination of manufacturers to depart from old methods, it has come with extraordinary suddenness, so much so, that it has caused consternation amongst the manufacturers of bisulphide of carbon and chloride of sulphur, whose business will suffer very severely unless new outlets are discovered for their products.

Until within the last two years the majority of rubber manufacturers used the "cold cure" process almost exclusively for the production of single and, to a considerable extent, in that of double texture waterproof garments, and as it was a process which had been gradually developing and increasing for years, its discontinuance was all the more surprising.

In Scotland the manufacturers have all adopted the "dry heat" process, but in England matters have not so far advanced in this direction, as some of the leading firms still cling to the "cold cure" as the safest and best process, but no doubt they will be forced to partially adopt it, as "dry heat" goods are now specially asked for.

The "dry heat" process has been very largely and successfully applied in America, and I think the Americans are to be congratulated as the first to thoroughly work it out, and it is mainly through their experience that manufacturers have been persuaded to adopt it in this country.

Perhaps, before we proceed further, it would be as well to look at the reasons which have brought about this change of front on the part of rubber manufacturers; and I think this can best be done by stating in a few words the advantages and disadvantages of each process. The advantages of the "cold cure" process were:—1st. The production of what is called a "transparent" proofing, which was and still is, though perhaps in a lesser degree, prized for single texture garments. 2ndly. The speed and cheapness of the process compared with the "dry heat." What I mean by cheapness here has nothing to do with the composition of the proofing, merely the cost for curing. 3rdly. The non-efflorescence of cold-cured goods, which is of much importance, and the reason of which has not been satisfactorily explained. Digressing for a moment, I shall mention one or two points in connexion with efflorescence which may be of interest. How is it that in cold-cured rubber we can have, say, 9 per cent. of sulphur present without efflorescence, when in the "dry heat" process 2 per cent. is dangerous? Some may say it is accounted for by the rubber never having been heated above the melting point of sulphur, but I tested this idea by heating pieces of cold-cured rubber containing more than 6 per cent. of sulphur above its melting point, but found no efflorescence. The following may be a possible explanation:—Some time ago a paper was read before the British Association by Thomson (1890, p. 785), in which he stated that when rubber was cold-cured it contained not only sulphur, but chlorine, the latter element being almost invariably double of the former. Now it occurred to me that the non-efflorescence of cold-cured might be accounted for by the sulphur and chlorine existing together in the rubber in combination.

Of course it might be advanced as a reason against such a theory that the greater part of the sulphur can be extracted with bisulphide of carbon, which fact I mentioned in a paper read before this Society (Jour. Soc. Chem. Ind. 1889, 368), but although such is the case, may not the chlorine be extracted at the same time and which would no doubt be the case if it existed as a compound. I am sorry at not having proved or disproved this idea, but want of time has prevented me.

Now, as regards the disadvantages of the cold-cure process:—

1st. The chief cause which led manufacturers to embrace the "dry heat" process, was the loss occasioned by damaged goods when using the cold-cure process, and the damage often arose from causes which, apparently, could not be explained. The blame was usually put upon the oil contained in cloth, but I think this was only occasionally the real cause, and my sympathy was often on the side of the cloth manufacturers, who usually, rather than lose a customer, paid the claim put upon them. No doubt

manufacturers often made mixings which were very unsuited for this process, but naturally preferred to throw the blame on other shoulders.

2ndly. The injurious action of the vapour of bisulphide of carbon on the workmen employed in attending to the "curing" machines. In some works this is reduced to a minimum and is not urged as an objection, but it is not the case in the majority of manufactories.

3rdly. It is put forward by the majority of firms that cold-cured goods do not stand hot or cold climates so well as could be desired, the strong light combined with the heat and perspiration from the body, exerting a powerful decomposing action in hot climates. The light is, I think, the chief agent in bringing about the mischief.

4thly. It is not possible to adulterate the rubber so easily when using chloride of sulphur as the curing agent, which in these days of low prices is of great importance.

My experience so far has been that a piece of rubber cold-cured properly, is the most perfectly vulcanised of any made, but the conditions which ensure say of a piece of sheet being so cured, are perhaps not possible in the case of proofed cloth, at any rate not easily attainable.

The advantages of the "dry heat" process are mostly implied by the disadvantages of the cold-cure process just mentioned, for—1stly. There is comparatively little claim for damaged goods, and cloths can be used containing a proportion of oil which would be inadmissible in the cold-cure process. Now, although the damage arising from the action of the cloth on the proofing is in the dry heat much reduced, yet it must not be inferred that it is entirely absent, as it is noticed with poor quality of black and brown cotton cloths that 12 months is about sufficient to cause the decomposition of good proofing. This is due to the mordants and dyes used. 2ndly. The use of bisulphide of carbon is avoided. 3rdly. The proofing is said to stand extreme heat and cold better than that made by the cold cure. 4thly. A cheap proofing can be worked.

As regards the disadvantages of dry-heat process, we have—

Firstly. The danger from efflorescence which has been the chief cause of complaint against manufacturers; and as black paramattas are coming more into fashion, this is a point of much importance.

Secondly. The large amount of stove space required to turn out a large quantity of waterproof cloth.

Thirdly. The cost per yard for curing is double that of the cold cure; no doubt this is made up for by being able to use a cheaper proofing, but it is a point in favour of the older process.

Fourthly. The non-possibility of producing "transparent" proofing which is distinguished from ordinary "dry heat" proofing by its softness and elasticity as well as its transparency.

It may be asked why not use the "steam" process for curing waterproof cloth when it is used for other goods; and the answer is that although it would cure the rubber well and with less danger of efflorescence than with "dry heat," yet it is fatal to the colours of the cloth and also to the cloth itself. Before the "dry heat" process came in, it was used, but never to a large extent except for black and white sheeting.

What is the "bon ideal" of a vulcanised process for waterproof cloth? This question is difficult to answer satisfactorily, but I should say it would be fulfilled by a process which in the shortest time and at the lowest temperature, consistent with a sound vulcanisation, would produce a proofing which would stand the hottest and coldest climates, and not effloresce, and at the same time could without unusual difficulties be produced at a cost which would enable manufacturers to use it even for cheap goods.

When manufacturers who had been accustomed to work with steam and cold-cure processes began to face the "dry heat" process, a few difficulties presented themselves, which were not easily overcome. For instance, if you take a piece of rubber mixed with 4 per cent. of sulphur, and heat to 250° F. in a "dry heat" stove, it becomes soft and unfit for use, but if the same piece were steam-heated it would cure up satisfactorily. To overcome this, quite a different

class of mixings had to be arranged to satisfy each quality of proofing. Again, the difficulty of avoiding efflorescence and at the same time get a satisfactory vulcanisation caused considerable trouble, and the experience was often gained through the loss of custom, because time is the factor which tells most forcibly as a test on rubber goods. Again, buyers who had been accustomed to purchase the finely-finished transparent garments with a velvety feel, and good elasticity did not readily take to single texture goods with dark proofing, and not so soft to the touch and with less elasticity. Of course, for light cloths it is not of great importance to avoid efflorescence, but for black or dark cloths it is necessary to avoid it completely. This efflorescence could be avoided by using a high temperature or a long-continued heat, but then the cloth suffered. In fact woollen cloth is found to "tender" slightly at 240° F., hence the importance of using a low heat and short time, both being consistent of course with a sound proofing. With ordinary "dry heat" proofing we cannot look for a lower temperature than 238° F., as sulphur melts at that heat; and anything below this is of no use; hence the obvious necessity of bringing up the heat of the stove as quickly as possible to this temperature. As regards the duration of the heat, it altogether depends on the composition of the proofing, but, as a rule, however, for good proofing 1—2 hours at 240°—245° F. reckoned from the time the temperature reaches 240° F. is about what is required.

The management and construction of the stoves requires considerable practical knowledge. Steam at 10 lb. pressure would be more than sufficient to produce a temperature of 238° F., assuming that no heat was lost by radiation and convection, but for large stoves nothing less than 60 lb. is used, and it is more economical to work with a still higher pressure, as the heat can be brought up more quickly to the melting point of sulphur, and so more work can be got out the stove in a given time.

About two years ago my firm was asked for a vulcaniser which would be suitable for the production of transparent proofing by the "dry heat" process, and as I thought such a thing quite feasible I had a series of trials conducted, which resulted in the production of a vulcaniser which answered the purpose, and has been found to be useful, not only for that special class of work, but also for other purposes which had not been anticipated. After completing the laboratory trials, the North British Rubber Company, who have had the longest experience in the "dry heat" process of any firm in Great Britain, kindly undertook the practical trials, and under the superintendence of Mr. A. Douglas have, during 1891, carried them to a successful issue, in so far that they have proved it suitable for the production of "transparent" proofing, and also have introduced it into the manufacture of other goods, such as fishing stockings.

Through their kindness, I am able to show you to-night samples of some of the goods which they are now producing, and the more important of which are the pair of fishing trousers which Mr. Douglas got made for his own use last October, and, although they have been in use since that time, are in very good order; also a new pair of fishing stockings, which show very well the nature of the proofing. The colour you will notice is odd, and can no doubt be improved, but what is wanted in these goods is a good tough proofing, irrespective of appearance. I am informed, moreover, that these stockings if damaged can be repaired, which is a special property. We have also two samples of transparent proofing, which serve to show the results which can be obtained in this direction.

I had hoped Mr. Douglas would have been present to-night to explain the chief points of difference between these sample goods and those made by other processes, but as he was prevented from coming he wrote to me, and, after giving a list of the articles, he goes on to say, "The fishing goods are spread with pure gum, with 4 per cent. of patent vulcaniser. They are heated for two hours, 50 minutes of that time being at 240° F. The rubber is exceedingly tough, more so than it would be by any other process, and the short and low temperature reduce the risk of tendering the fabric very considerably."

The two "transparent" samples are spread with the same gum as the fishing stockings. The silk one was spread July 1891, and vulcanised three-quarters of an hour at 240° F.; whilst the union silk was spread last week, and heated one hour 240° F. This gum, more particularly in very light spread goods, has a very soft and agreeable feel, and looks well, but I am afraid the high price of your patent vulcaniser will seriously interfere with its adoption by manufacturers for the single texture waterproof garment trade, which is to be regretted, as I consider it the best form of vulcanisation at present known for these goods."

I have here also samples of coloured sheet-rubber, kindly prepared for me by Messrs. W. Warne & Co., which contain only 2 per cent. of vulcaniser. The vulcanisers used in these trials were the iodides of the heavy metals mixed with sulphur.

In my patent I claim all iodine and bromine compounds, but so far, have found those of the heavy metals to give the best results. The addition of sulphur was found to be necessary, as without it it was impossible to obtain good results.

The points which were forcibly brought out during the trials were:—1st. The very small percentage of compound which was necessary to ensure complete vulcanisation. The iodide could be reduced to 1½ per cent., whilst the sulphur was 2 per cent., and you can well understand that 3½ per cent. of compound would not affect, to any extent, the transparency of the rubber. 2ndly. The low heat required for complete vulcanisation. This seems a very important point, as most manufacturers experience great difficulty in getting a satisfactory "cure" at a temperature which does not injure the cloth. The extreme sensitiveness of the vulcaniser to heat caused a little trouble at the commencement of the trials, as they were conducted too much on the lines of the ordinary "dry heat" mixings. I remember the first trials which were made had as much as 15 per cent. of the iodide and 6 per cent. of sulphur, and the astonishing thing was, that these samples cured at 200°–205° F., considerably below the melting point of sulphur, which was very unusual, and proves that whatever action takes place it does so in a manner quite different from the ordinary process in which no action is apparent below 238° F., although a considerable proportion of the "curing" agent is present. Of course when using such a high percentage of the vulcaniser you can naturally imagine that a large proportion remains unexhausted, and is ready to still further affect the rubber. This was proved by heating a piece of such rubber to 240°–245° F. for but 39 minutes, when it became quite hard. The property possessed by this vulcaniser of exerting a curative effect considerably below 238° F., although of little practical importance at present, may at some future time receive useful application. 3rdly. The quickness of the cure was rather surprising, as one half hour was sufficient when using 3 per cent. vulcaniser and 2 per cent. sulphur, and when using a high percentage along with a high temperature the "cure" was effected in a few minutes. With 15 per cent. ten minutes at 250° F. would suffice.

A quick cure is regarded by some rubber authorities with suspicion, and, I think, naturally, as the ordinary method employed, and which must force itself upon the mind for comparison, does not cure under two hours at 238° F. I found that with this new compound it was safest to use a small percentage and lengthen the heat, but an hour seemed sufficient for all ordinary purposes, using say 2–3 per cent. with 2 per cent. of sulphur. With these proportions the curing agent seems to be exhausted after one hour's heating. To prove this, a piece of mixed rubber was cut into two pieces: one was heated for one hour at 240° F., and the other for five hours, when they were both equally cured, showing that with the extra three and a half hours heating no further effect was produced. The fact of the vulcaniser curing so quickly and at such a low temperature is a saving, in that more work can be got out of a stove in a given time, which is of considerable advantage in the "dry heat," as large stoves are required to put through a large quantity of cloth.

The continuous stove patented by Waddington, and worked by Messrs. Charles Macintosh & Co. and others, through which the cloth is slowly drawn, ascending and descending many times before it is finally wound upon a roller on the outside, seems to be a move in the right direction, as by this system the cloth can be tested occasionally, and the speed of the rollers regulated according as to whether the proofing is over- or under-cured; it also prevents the creasing and marking of the proofing, which is a common occurrence in ordinary stoves. This system of curing would be specially applicable when using this new vulcaniser, seeing it is more sensitive to heat than that used for ordinary work.

Whilst working with this vulcaniser a difficulty presented itself which caused some trouble, although a simple remedy was found to obviate it. When working with woollen and almost all kinds of union tweeds, the proofing cured up quite satisfactorily, but when working with cotton cloths containing black and brown dyed yarn the proofing became tacky and refused to cure quite satisfactorily. It was very noticeable with, say, a piece of black and white check cotton cloth, because wherever the proofing was upon the black squares it was soft and under-cured, but upon the white squares it was quite cured, and in every respect satisfactorily. Seeing that black woollen cloth was free from this peculiar action, it could only be caused by the different manner in which the dyes were fixed in the two cases. In the case of the cotton, the mordanting material was thought either alone or in combination with the dyestuff to cause the mischief. It being difficult to tell what colours were to blame in cloths containing many colours, I procured cotton-dyed yarn of different colours, and got them knitted into strips, which were then spread with rubber dough containing a proportion of vulcaniser which was known to be more than sufficient to cure it. After curing for two hours at 240°–245° F., the proofing on the white, blues, drabs, and certain shades of brown was quite vulcanised, but on the black and dark browns it was under-cured.

As the black cloth had caused the most trouble, attention was specially directed to it, to find out, if possible, the cause of this action. In the first place the opinion of an experienced dyer was taken as to the probable process used in dyeing the yarn. After a critical examination he reported that the mordant was iron liquor, the "prepared" tannin, and the dye logwood. Three pieces of white cotton cloth were next taken, and after well scouring and drying treated as follows:—

No. 1	soaked in a solution of iron liquor.
" 2	" " " tannic acid.
" 3	" " " logwood.

They were now dried and spread with rubber dough of same composition as that previously used. After drying they were cured two hours at about 240° F., and it was found that in each case the proofing was sound, so separately the reagents did not interfere with the curing. Next, three pieces of cloth were taken, scoured, and treated as follows:—

No. 1	dipped iron liquor, afterwards tannic acid.
" 2	" " " logwood extract.
" 3	" " " then tannic acid, then logwood extract.

After drying they were spread with rubber dough and cured as before, when No. 1 cured, but not Nos. 2 and 3, proving apparently that it was the compound produced between iron oxide and colouring matter of the logwood which accounted for the mischief. Want of time prevented me from going further into the matter, and trying if possible to find what the cause of this action was, i.e., how could this dye compound so influence the iodide or the mixture of iodide and sulphur as to retard its curative action. It almost looked as if the dye compound so affected or combined with the sulphur as to render it less available for the iodide, as the addition of extra sulphur was found to be an antidote as regards the curing, but was inadmissible when working with black cloth because of danger from efflorescence. It was suggested, as a probable explanation, that the tweed cloths which are usually sold might contain some of the

mordant unwashed out, or greasy matter, so pieces of such cloths, containing a good admixture of black and brown were treated as follows:—

- No. 1.—Treated three times with ether, to remove grease.
- No. 2.—Boiled three times in water.
- No. 3.—Boiled weak acid, then water.
- No. 4.—Boiled weak alkali, then water.

After drying they were spread and cured two hours at 240° F., but the proofing was useless, which disproved the theory of grease or mordanting material being left in the cloth.

It has long been known that copper and certain of its compounds exert a deleterious effect on rubber, and this was brought forward lately by Thomson (India-rubber Journal, 1891, 328), but in the above examples copper was absent.

I asked Mr. Christie, of Messrs. J. Orr Ewing & Co., who has had a large experience in the dyeing of cotton yarn, if he could offer an explanation, and he thought the reason might be the presence of peroxide of iron, and suggested the procuring of a piece of buff cotton cloth, much used for window-blinds, and which, he said, would be free from all foreign matter, such as tannic acid and logwood, used in dyeing black and brown yarn. I did this, and found that the action of the vulcaniser was retarded, almost proving that the iron oxide was the cause of the mischief; but if this were proved, the next question would be, what is the reaction which takes place? Although this action was peculiar, and, in the meantime, to me inexplicable, yet a simple remedy was found to allow of its being used on cotton cloths. This consisted, in the first place, in giving the cloth a coat of pure rubber dough, mixed with 2 per cent. of sulphur, and which is often resorted to in ordinary "dry heat" process to avoid "efflorescence."

The action of dyed cloth on rubber proofing is an important question, not only for the rubber manufacturers but also for dyers, and it seems to me that the solving of the problem should not be left to manufacturers, but to the dyeing schools, who, so far as I know, have given the matter little or no attention, and some of the wealthy rubber manufacturers could, with advantage, encourage the investigation of such questions in the technical schools.

An important point in connexion with the use of this new vulcaniser is, that by its means coloured rubber proofing can be easily obtained without adding a large amount of pigment to the rubber. In the ordinary "dry heat" process it is difficult to get a good coloured "proofing," and at the same time keep the proportion of compound so low that it will be elastic.

With this vulcaniser, however, brown, drab, red, blue, and green proofings can be obtained.

I have here a few samples of coloured proofings which Messrs. Campbell, Achnach, & Co., kindly prepared for me, and you can judge better of their appearance and softness to the touch by inspection.

Of course, if wanted, the pigment can be increased, as I have had 360 per cent. added, as per sample shown, and still the rubber was strong and elastic.

The coloured proofings cured up in a time according to the percentage of vulcaniser and compounding material added, but the usual time was three-quarters of an hour at 240°–245° F.

It mixes very well with most pigments, but there are some which retard its action. It appears to me that proofing cured with it could be finished without farina, as the surface after curing is very dry and soft, and, if so, it would be a point in its favour, as farina seems to exert a deleterious action on the surface of the rubber, no doubt through its getting damp and fermenting; besides, farina comes off when wet upon the cloths, and leaves marks, which is objectionable.

Two most important questions in regard to the introduction of this new vulcaniser are, as to its keeping qualities and its cost.

Firstly. As regards its durability, it is impossible to give an answer based on long experience; but when one takes into account the fact that the samples which were made in the preliminary trials 15 months ago are still in good condition, it is surprising, as too much vulcaniser was

used, and the method of working has been much improved. There can be no question, I think, that the "transparent" dry-heat proofing will stand better than that cold-cured in warm climates. To test their heat-resisting properties, a piece of each of these kinds of proofing, and also a piece of that which had been cured by ordinary "dry-heat" process were taken and heated to 306° F. for half an hour. The cold-cured piece was simply rotted away; the ordinary dry-heated piece had quite decomposed, whilst that cured by the new vulcaniser was but slightly so, showing that it was not readily affected by heat. Judging from my own experience, and the interchange of opinion I have had with Mr. Douglas and others, I conclude that there is every probability that the rubber will keep as well as the ordinary "dry heat" rubber.

Secondly, as regards the cost. At first sight it would appear as if the cost would be such as to preclude it from general use, but on looking more closely into the question it wears a different aspect. Taking the average weight of "transparent" proofing on a coat at 2 lb., we have for this weight 4d. worth of vulcaniser. Now there falls to be deducted from this the cost of curing by the ordinary method, which is about one penny, and we must also take into account that by the rapid curing a considerable saving is effected, so the difference in price is certainly not prohibitive. If it is compounded, of course the price can be reduced to that of ordinary curing.

It may be asked, will this compound mix with rubber substitutes, and I may say that the ordinary oil substitute made with chloride of sulphur is quite as unsuitable as it is for all "dry heat" work. Oil vulcanised with sulphur by heat is suitable, but the admixture of different substances is one which only can be determined by the manufacturers themselves.

The cheapening of rubber by adding different foreign materials has become quite an art, and a necessary one, no doubt, and something will soon be found which will serve as an article to cheapen the mixing with the new compound also. It has been tried for double as well as single texture garments, and is very serviceable where a nice pliable proofing is wanted and when a cloth is being dealt with which is easily affected by heat.

It is principally in connexion with "dry heat" that it has been tried, but it gives good results in the steam heater when wrapped up to protect it partially from the steam. I have here a piece of sheet rubber cured 2½ hours at 260° F., which shows that by this process it is possible to bring about good vulcanisation, as the rubber, you will notice, is very strong.

My best thanks are due to Mr. Anderson, who conducted all the experimental work involved in testing the properties of this new vulcaniser; and also to Mr. Douglas, Mr. Burbridge, and Mr. Cairns, for their kindness in preparing samples and giving valuable advice.

DISCUSSION.

The CHAIRMAN said that he thought it would be difficult to exaggerate the value of this paper. Mr. Fawsitt seemed to have made a remarkable discovery in the vulcanisation of rubber. He should like to ask what particular iodide he used.

Mr. J. W. BIGGART said that Mr. Fawsitt remarked that light seemed to have an injurious effect upon the rubber, as instanced in the case of the goods hanging in a shop window. This seemed to indicate that a chemical change took place under the influence of light, and he should like to ask what change it was that actually did take place.

Mr. FAWSITT, in reply to the Chairman, said that the iodide used in all the trials for the fishing stockings and other specimens shown was iodide of antimony. They fixed on that in preference to iodide of tin because antimony was a cheap material and produced good results; iodide of tin also gave good results; but seeing they had commenced with antimony, they did not wish to alter meantime. Regarding the reaction which took

place in the vulcanisation, he had never formed a satisfactory opinion on that point, as they had not had time to go into the subject fully.

With reference to the question asked by Mr. Biggart as to the effect of the rays of the sun on the proofing, he could not give particulars of the chemical change that took place.

ON THE COMPOSITION OF "HUNYADI JANOS" MINERAL WATERS.

BY J. W. BIGGART.

THAT the mineral waters as a class occupy a very important place in *Materia Medica* is an acknowledged fact. Regarding the properties of many of them there is a common belief that to the waters as found in nature belong qualities which art cannot reproduce by any of its preparations or imitations. Many medical men hold this opinion, and for obvious reasons it is a notion suggested and encouraged by all those who have a proprietary interest in any of the wells.

While it is here granted that the artificial waters must and will differ in properties from the natural, if any of the various radicles in the artificial imitations be brought together either in a different order or in different amounts from that which they hold in the natural water, still it is hard to see, how, if these combinations and the gases present in the water be exactly known and the data deduced from them correctly followed, there can or will be any difference between the medicinal qualities of a natural water and its artificial imitation. In short, if the salts present and their amounts be known then the water can surely be prepared. It is on one of these natural mineral waters called "Hunyadi Janos," that this short note and analysis have been prepared, and it may be of some interest to state that it is one of the most popular aperient waters having a sale which is reckoned by several million bottles per annum.

Concerning this water, the writer has heard it repeatedly stated (by medical men) that it possesses properties so peculiarly its own that they cannot be reproduced by art, but, discrediting such a theory, its analysis and examination were undertaken.

The generally accepted opinion concerning the composition of the water is that it contains principally magnesia and sodic sulphates and chlorine combined with sodium as common salt.

For the most part this opinion has been verified, but in one respect, namely, the state of combination of the chlorine, a vital and important difference has been observed, as shall be presently pointed out.

The analysis of the salts left on evaporating a portion of the water gave the following percentages of the different radicles:—

Basic.		Acid.	
Soda	1.00	Silica	Trace.
Magnesia	0.535	Sulphuric acid....	2.32
Lime	0.18	Chlorine	0.101
Iron	Trace.	Phosphoric acid...	Trace.

On looking over these results it is apparent that all the lime must first be calculated to sulphate. After this it is necessary to discover to what base or bases the chlorine is linked. Then it only remains to calculate soda and magnesia left to sulphates. As the condition of the chlorine is the only point which presents any difficulty, the particular state of its combination was arrived at in the following manner:—A measured volume (50 cc.) of the mineral

water was evaporated spontaneously in the air (this precaution was adopted to ensure against any double decomposition taking place between the salts).

After evaporation the salts were taken up with absolute alcohol, which dissolved the chlorides present, but left the sulphates as an insoluble residue. The alcoholic extract was next evaporated to dryness (also in the air) and the residual mass taken up as before. The acids and bases present in this solution were then estimated, and they were found to be practically pure magnesium chloride. Proceeding on these data, and linking the proper bases to their own acids, calculation showed the composition of the water to be as follows:—

	Parts per 1,000.
Calcic sulphate.....	0.41
Magnesian do.	16.05
Sodic do.	25.00
Magnesian chloride.....	1.20
Silica	0.12
Water.....	957.22
	<hr/> 1,000.00

DISCUSSION.

The CHAIRMAN said that the composition of these mineral waters was extremely interesting, and the one which was the subject of this paper was perhaps the most interesting of all. It seemed that waters the same as this and to have the same effect could be artificially made. It was well known that for many years there was a German spa at Brighton, where the waters made were an exact imitation of many of the German natural waters. He had used Hunyadi Janos water in his own house for many years, but had always prepared it himself, and never could find any difference from the natural water. He knew that the composition of the artificial water was always the same, and the natural water was not. He should like to ask if Mr. Biggart found no potash salts in this water, as he understood that there was always small quantities of sulphate of potash and of bicarbonate of soda present?

Mr. T. L. PATTERSON did not think that Mr. Biggart's method of analysis proved conclusively the presence of magnesium chloride in Hunyadi Janos water, as there was no doubt that chemical changes might take place on addition of absolute alcohol to the mixture of salts, resulting in the formation of easily soluble magnesium chloride.

Dr. G. G. HENDERSON agreed with Mr. Patterson in thinking that Mr. Biggart's analysis left it doubtful whether magnesium chloride was present in the natural water. He should like to know whether the dissolved gases had been estimated. He thought there was a large field open to manufacturers of mineral waters, for it would be quite unnecessary in many cases to go to German spas, or to buy the foreign mineral waters imported into this country in such enormous quantities, if these waters could be prepared artificially at home. There ought to be little difficulty about this, seeing that the composition of most of the waters was well known.

Mr. BIGGART, in reply to the Chairman, said that he had examined the residue for potash salts, but had failed to detect them. He had not estimated the dissolved gases.

any desired proportion, at the moment when it enters the valve-box of the cylinder. For this purpose steam is taken from the boiler through a separate pipe, and carried to a superheater fixed in the smoke-box of the boiler, or heated in any other convenient manner, and thence taken through another pipe to join the saturated-steam pipe, suitable valves being inserted for the regulation of the supply.—B.

A Method and Apparatus for subjecting Liquids having Substances suspended in them to Centrifugal Action, whereby they are brought in Contact only with Sterilised or with other Air, with which they are to be Saturated. O. Imray, London. From A. Bergh, Copenhagen, Denmark. Eng. Pat. 19,071, November 24, 1891.

In the applicant's specification, No. 86, 1891, is described a centrifugal apparatus applicable mainly for treating worts and beer, and a method of so conducting the brewing process that they may be brought into contact with sterilised air only. It is now claimed in the above patent that this method is of great importance in the treatment by centrifugal action and aeration of various other fluids, water, blood, milk, oil, yeast, wine, and spirits. The two last should, however, be first heated to render them capable of taking up more air.

Any gas which mixes readily with the liquids treated, and saturates them may be substituted for sterilised air.

Drawings accompany the specification.—L. de K.

PATENTS.

Improvements in the Methods of Heating Liquids, and Generating and Utilising Vapour for Motive Power and the like Purposes, and in Apparatus and Appliances connected therewith. W. H. Watkinson, Sheffield. Eng. Pat. 4596, March 14, 1891.

THE principal novelty involved in this patent consists in loading steam or vapour with liquid in the form of spray or with gaseous matter, for the purpose of diminishing the speed of the issuing steam when acting upon motive power engines of the rotary kind, such as steam turbines, whereby the economical speed of the turbine can be reduced to a more practical limit than has hitherto been attained. The heating of the liquid for the production of steam is accomplished in a heater consisting of narrow cells, in which almost every particle of the liquid is brought in direct contact with the heated walls. The rest of the specification refers principally to the mechanical arrangements involved in carrying out the above objects of heating and spraying the liquid, and mixing the spray with the issuing vapour.—B.

Improvements in the Drying or Superheating of Steam, and Apparatus therefor. T. Mudd, West Hartlepool. Eng. Pat. 5783, April 3, 1891.

THE use of superheated steam in steam engines has hitherto failed owing to the mechanical difficulties encountered through the destruction of the working surfaces, the superheater not being under proper control or adjustment. The patentee proposes to overcome this difficulty by superheating only part of the steam, and mixing it with the saturated steam in

II.—FUEL, GAS, AND LIGHT.

Sulphocyanogen in Coal-Gas. J. V. Esop. Chem. Ind. 1892, 15, 6—10.

THE formation of cyanogen and its derivatives by the destructive distillation of coal is attributed by de Romilly to the conversion of the ammonia into ammonium cyanide at a bright red heat in the presence of carbon. The quantity thus generated depends on the mode of carbonisation. According to Gasch, retorts worked with heavy charges give the largest proportion. If the products of distillation, after leaving the retort, are kept at a sufficiently high temperature, ammonia and cyanogen are found in the gaseous mixture in a free state. If, however, the temperature is allowed to fall below 80°, which is the case in the purification of coal-gas, ammonium cyanide, ammonium thiocyanate, and ferrocyanides are formed. Of the aqueous liquids deposited in the condenser during the manufacture of gas, it is here necessary to consider only ammonia and thiocyanic acid. German gas-liquor obtained from Saar and Ruhr coal gave by analysis:—

	CNSH	NH ₃
	Grms.	Grms.
Gas liquor from Wiesbaden	1.22	18.05
Gas liquor from Karlsruhe	1.51	19.03
Gas liquor from Mainz	2.33	36.05

In the purification of gas by chemical treatment free sulphur, thiocyanic acid, ammonia, and potassium ferrocyanide are the most important constituents to which it is necessary to direct attention in the present paper. The following table gives the percentages of thiocyanic acid,

* Any of these specifications may be obtained by post by remitting *sd.*—the price now fixed for all specifications, postage included—to Sir Henry Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

ammonia, and potassium ferrocyanide contained in gas-purifying material saturated with these impurities:—

If this material be stored in the cold protected from atmospheric influences, and in layers of moderate dimensions, it may be kept for some time without suffering decomposition. If, however, stored in large masses the temperature gradually rises, the green colour changes to red, acid fumes are liberated in the course of a few days, and finally the sulphur ignites and burns away. At this stage the decomposition of thiocyanic acid has reached its maximum, only about 0·5 per cent. remaining unchanged. A portion is converted into ferrocyanide, and the remainder is wholly decomposed. The quantity of ferrocyanide is thereby increased from 4·3 to 7·2 per cent. The extraction of thiocyanic acid is effected by lixiviating the exhausted purifying agent and evaporating the aqueous extract in enamelled pans. Ammonium thiocyanate crystallises out

and this is then decomposed by the addition of alkalis (hydroxides) or soluble alkaline sulphides. From weak extracts or solutions highly charged with chlorides, sulphates, sulphites, &c., it is preferable to precipitate the thiocyanic acid by means of a cuprous salt and decompose the thiocyanate thus obtained by the addition of a soluble alkaline sulphide. The resulting cuprous sulphide is roasted, the oxide dissolved in hot dilute acid, and the solution used for the precipitation of a fresh portion of aqueous extract. To obtain pure ammonium thiocyanate the crude salt is recrystallised, having been previously treated with barium sulphide. A chemically pure product is obtained by carrying out the process expressed by the equation $(\text{CNS})_2\text{Ba} + (\text{NH}_4)_2\text{SO}_4 = 2 \text{NH}_4\text{CNS} + \text{BaSO}_4$. Barium thiocyanate is obtained from the ammonium salt by the addition of barium hydroxide or preferably barium sulphide. The decomposition is effected in a closed vessel fitted with mechanical stirrers and heated with steam under slight pressure (0·2 to 0·4 atmosphere) to a temperature of 80°–90°, the ammonia being driven off as rapidly as possible. The barium salt may be obtained also from cuprous thiocyanate by fractional precipitation, the undecomposed portion being treated with an excess of barium sulphide, and the resulting solution evaporated after the removal of all traces of metal and barium sulphide. The calcium salt is prepared from the ammonium salt by the addition of calcium hydroxide, ammonia being liberated. The solution is evaporated to 45° B. and allowed to cool when the calcium salt crystallises out in deliquescent but well-defined needles. The potassium salt is obtained by the addition of potassium sulphate or carbonate to alkaline thiocyanates or by precipitating ammonium or cuprous thiocyanate with potassium sulphide. The aluminium salt is prepared by decomposing the calcium or barium salt with alum free from iron.—D. B.

Geological and Economical Conditions of the Westphalian Coal-Beds. Brookmann. J. für Gasbeleuchtung, 1891, 34, 633–636.

AFTER giving an account of the development and present condition of the coal-fields of Westphalia, the author proceeds to consider the classification and nature of various kinds of coal, pointing out at the same time that the terms which he employs are purely relative and only apply to Westphalian coal.

In the following table the percentage of carbon, hydrogen, and oxygen in various carbonaceous deposits, calculated on the ash- and water-free substance, is given; the quantity of available hydrogen, and the yield of coke are given in the fourth and fifth columns respectively, whilst in the sixth column the geological period to which the coal belongs is stated; in the seventh column the products of the natural distillation of the coal are given:—

—	C	H	O	Available H	Coke.	Period of Formation.	Distillation Product.
Wood	44	6	50	..	15	} Present	{ H ₂ O CO ₂
Turf	60	6	34	2	20		
Lignite	65	6	28	3	40	Tertiary	C ₂ H ₆
Forest coal	70	6	24	3	45	{ Chalk	C ₂ H ₆
						{ Jurassic	CH ₄
Flame coal	75	6	19	4	50	} Carboniferous	{ CH ₄ CH ₄ + H ₂ CH ₄ + H ₂ CH ₄ + H ₂ CH ₄ + H ₂
Gas coal	80	6	14	4	60		
Coke coal	85	5	10	4	{ 70 80		
Poor coal	90	4	6	3	50		
Anthracite (coke)	95	2	3	2	85		
Graphite	100	100	Silurian.	

It will be seen from the table that the percentage of carbon increases, whilst that of oxygen decreases, with the age of the deposit, whereas the percentage of hydrogen undergoes no material alteration. This change in composition which takes place in the earth is similar in some ways to that which occurs in gas-making; in the first stages of the distillation of coal the gases evolved are highly luminous, but as the process continues the gases lose their luminosity and finally consist almost entirely of hydrogen.

The quality and the quantity of the coke depends to a great extent on the chemical composition of the coal; an anthracite coal, for example, gives only a loose powdery coke, whereas ordinary gas-coal yields, as a rule, a good cake of porous coke. The colour of the coke obtained from various kinds of coals is very characteristic, and affords a means of estimating the geological age of the coal when other criteria fail.

The quality of a coal may also be judged by its appearance; on examination it will be found that even in coal from the same stratum considerable differences may be observed. In some samples lustrous deep black lines are seen, indicating, as a rule, a low gas-producing power and a low percentage of ash; also greyish black stripes of coal which has a high gas-producing power, but which, at the same time, contains a large percentage of ash. Mineral wood-coal, a non-cokable, fibrous coal, of low gas-producing power and rich in ash, is a very frequent constituent of coals; stripes or layers of cannel, pseudo-cannel, shale, &c., are also frequently met with in one and the same sample, the quality of which will, of course, depend on the predominance of one or other of these varieties.—F. S. K.

New Researches on the Heat of Combustion of Coal, determined by Means of a Calorimetric Shell. Scheurer-Kestner and Meunier-Dollfus. Bull. Soc. Ind. Mulhouse, 1891, 577—589.

THE authors describe some experiments which they carried out with the object of verifying results obtained by them with a Favre and Silbermann calorimeter. The apparatus used was Berthelot's calorimetric bomb, which was placed at their disposal. This consists of a metal shell lined with platinum (to resist chemical action), in which combustion can take place, and an ordinary calorimeter of about 2 litres capacity in which the shell can be suspended, and by means of which the heat developed is observed. The substance to be experimented upon is weighed and suspended within the shell in a perforated platinum capsule. Immediately above this is placed a spiral or fine iron wire, through which a current of electricity can be passed. The lid of the shell, which can be screwed in its place, carries a valve, by means of which oxygen at a pressure of 25 kilos. can be admitted to the interior. This having been done the shell is placed in the calorimeter and the temperature of the whole is allowed to become uniform. The temperature is then observed from minute to minute and a current is sent through the spiral. This, as it heats, sets the combustible on fire. Combustion is sudden and complete, leaving *no combustible residue*. The temperature should be observed during several minutes, but the whole operation is over in a quarter of an hour.

The advantages of the method are (1) simplicity of apparatus, in consequence of which a single experimenter is sufficient, whereas at least two were required with the older apparatus, (2) economy of time, and (3) owing to complete combustion the corrections to be applied are of a lower order than those necessary with the apparatus of Favre and Silbermann. The principal drawback to the use of the new apparatus is in the cost, both of the platinum lining to the shell and of the reservoir for compressed oxygen. When the substance to be experimented upon is coal, it presents the further disadvantage that it is not possible to weigh the ashes. These are scattered by the violence of combustion about the walls of the shell, and, further, it must be remembered that they are soluble in the sulphuric and nitric acids formed during combustion. Their amount can, however, be estimated by determining the amount of the ashes formed in burning known weights

of the same coal. Another source of error arises from the heat of formation of sulphuric and nitric acids, which although negligible in approximate work, must be allowed for if great accuracy is desired. The amount of these bodies formed during combustion is estimated by titration with an alkali, and the heat developed in their formation is calculated by Dulong's law. It is also necessary to allow for the heat generated in the spiral by the current, which, for the particular spiral used, was estimated at 22 calories.

On the whole the authors are of opinion that the results obtained by this method are more reliable than those obtained by the older methods, as the necessary corrections are of so much less relative importance.

In order to make the correction for radiation as small as possible, the calorimeter was placed within a large double calorimeter, the space between the walls of which was filled with water. By this means the correction for radiation was reduced from 0.002° to 0.001° per degree per minute. The authors also found that when the coal was used in pieces instead of in powder, it was possible to obtain complete combustion. In the latter case it was necessary to dilute the oxygen with air, pure oxygen giving rise to explosions which always left a combustible residue.

In general, the results obtained by this method give a lower value for the calorific power than those obtained by former methods. The following table gives the results of an experiment with a particular sample of coal:—

Weight of substance	Gm.
Initial temperature	11°735 ²
Temperature at end of 1st minute	11°000 ²
" " 2nd "	11°600 ²
" " 3rd "	11°650 ²

	Calories
Thermal capacity of calorimeter.....	2,400
$2.954^{\circ} \times 2,000 =$	7,059
Deducting for heat generated in spiral...	<u>22</u>
	<u>7,067</u>

$$\frac{7.067}{0.943} = 7,494 \text{ calories per unit weight of the coal.}$$

The mean of several determinations of the composition of this sample showed that only 87 per cent. of it was pure coal.

$\frac{7,494}{87} \times 100$ gives 8,620 calories per unit weight of pure coal. This number is 326 less than that obtained in former experiments by the authors. The authors have also arrived at the conclusion that it is impossible to calculate the heat of combustion of a specimen of coal from its composition. Appended are the observed and calculated values for three samples of coal.

	Calories.
1. Calculated by Dulong's law	8,382
Calculated from total amounts of carbon and hydrogen present	8,706
Observed	8,697
2. Calculated by Dulong's law	8,082
Calculated from total amounts of carbon and hydrogen present	8,501
Observed	8,264
3. Calculated by Dulong's law	8,513
Calculated from total amounts of carbon and hydrogen present	8,685
Observed	8,700

The authors consider that they have proved (in conformity with their earlier researches) that some kinds of coal have a heat of combustion which is greater than that of the carbon and hydrogen which they contain; the heat of combustion of others is less than this, although it is sometimes higher than the heat calculated by Dulong's method.—D. E. J.

Note on the Carbon deposited from Coal-Gas Flames.
W. Foster. Proc. Chem. Soc. 1892 [108], 46.

The author quotes analyses of cokes obtained by carbonising sugar and starch:—

Cane Sugar Coke.—High temperature, carbon 95.0, hydrogen 1.1; low temperature, 94.1 carbon, 1.2 hydrogen.

Starch Coke.—95.0 per cent. carbon, 0.9 per cent. hydrogen respectively.

From the similarity in composition of these cokes to that of the soot obtainable from coal-gas flames, he is of opinion that there is a resemblance in the general character of the chemical processes whereby they are formed.

The Origin of Acetylene in Flames. V. B. Lewes. Proc. Chem. Soc. 1892, [108], 47—48.

The author has sought to determine whether acetylene is the product of high temperature change or of oxidation. The experiments described consisted in passing hydrocarbon gases and mixtures of such gases with others through a heated platinum tube 2 mm. in diameter, which, judging from experiments made to test the point, would seem to be without special action.

On passing methane alone through the tube while a length of 6 in. was heated to 1100° in the flat flame of a broad Bunsen, a product was obtained containing 3.2 per cent. of unsaturated hydrocarbons and 1.8 per cent. of acetylene. The effect of heating methane with other gases is indicated by the following figures:—

	3 per Cent. Oxygen.	15 per Cent. Air.	50 per Cent. Carbon Monoxide.	60 per Cent. Hydrogen.
Unsaturated hydrocarbons.....	2.0	2.0	1.0	1.47
Acetylene.....	1.423	0.656	0.887	0.473
Carbon monoxide.....	1.1	1.0	..	0.490

These results appear to point to acetylene being formed by the action of heat alone.

Ethane heated alone gave a product containing 19.47 per cent. unsaturated hydrocarbons and 3.221 per cent. of acetylene. The effect of heating ethane, diluted with 30 per cent. of hydrogen with air was as follows:—

	15 per Cent. Air.	20 per Cent. Air.	25 per Cent. Air.
Unsaturated hydrocarbons..	7.60	5.78	5.05
Acetylene.....	3.30	3.20	3.11
Carbon dioxide.....	6.00	1.01	1.51
Carbon monoxide.....	1.54	2.53	3.03

The effect of temperature on the formation of acetylene is well shown by the following results obtained on converting Russian petroleum into oil-gas in a Patterson retort:—

Temperature of retort....	500°	700°	800°	900°
Yield of gas per gallon of oil.	12 c.p.	60 c.p.	72 c.p.	81 c.p.
Illuminating power.....	54.8	50.7	57.1	42
Unsaturated hydrocarbons	39.13	36.56	36.55	22.04
Acetylene.....	0.052	0.084	0.38	0.46

PATENT.

Improvements in Machinery for the Manufacture of Peat Fuel. B. G. B. Mills, London. From E. L. Clarke, Montreal, Canada. Eng. Pat. 5980, April 7, 1891.

THE machinery patented consists essentially of a cylindrical mould with a flat-headed screwed revolving plunger, the peat to be compressed into fuel being fed through a hopper on to the screw and compressed into the mould by the head of the plunger. The plunger is actuated by a spindle co-axial with it, to which is communicated a revolving motion to cause the travel of the peat by means of the screw thread, and a longitudinal motion by means of an eccentric driven by a shaft at right angles to that by which the revolving motion is communicated. This arrangement is preferably worked in duplicate, a single central shaft then sufficing to actuate two plungers parallel with itself. The pinion upon the central shaft is sufficiently wide in the face to allow of the reciprocating movement caused by the action of the eccentric to take place without the teeth becoming disengaged. A wooden resistance block is inserted into the mould at the beginning of the compressing operation, its place being afterwards supplied by the peat itself. The thread on the plunger is kept clear by means of a worm wheel working at the bottom of the hopper. The apparatus described is used in connexion with the preliminary disintegrating and drying machine, in which the peat after having been freed from sticks is carried through a cylinder, through which furnace gases are caused to pass, by means of a rotating longitudinal shaft fitted with stirrers, and driven by the same gear as gives motion to the compressing machinery. It is claimed that the heat generated in compressing the peat aids its agglomeration by bringing "to the surface the tarry residue inherent in the peat particles."

—B. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Paranthracene. K. Elbs. J. Prakt. Chem. 1891, 44, 467—469.

In 1866 Fritzsche discovered the transformation of anthracene into paranthracene by prolonged exposure to sunlight and recommended this reaction as a suitable means of preparing pure anthracene. The author obtained this hydrocarbon by exposing a saturated solution of anthracene (90 per cent.) in benzene (at 40° to 60°) to the action of sunlight for one week, the solution being heated on a water-bath from time to time for the purpose of re-dissolving any anthracene which may crystallise out. The deposit was filtered off, boiled out with a small quantity of benzene and recrystallised from hot xylene or dimethylaniline. From the former paranthracene separates in colourless lustrous needles, whilst dimethylaniline gives it in the form of laminae. Both melt at 272°—274° with complete conversion into anthracene. Paranthracene possesses no fluorescent properties, and its solution in dimethylaniline may be heated

without change. On prolonged boiling in naphthalene it is, however, gradually converted into anthracene, the change being observable by the original colourless solution assuming a violet fluorescence. It is only sparingly soluble in most solvents. At the temperature of its melting point glacial acetic acid, phenol, thymol, resorcinol, quinol, paranitrotoluene, (1 : 2 : 4)—dinitrotoluene, α -nitronaphthalene, acetanilide, acetoparatoluidide, salicylic acid, and diphenyltrichlorethane dissolve 0.1 per cent. or even less; α -naphthylphenylketone, nitroscendoenene, and diphenyl from 0.1 to 0.2 per cent., and naphthalene, acenaphthene, azobenzene, diphenylamine, and triphenylmethane from 0.2 to 0.3 per cent. Owing to the fact that a solution of paranthracene in naphthalene saturated at the temperature of its melting point was found to contain only 0.229 per cent. of paranthracene, the depressions to be observed are obviously so small that in order to minimise the error as much as possible the results should be calculated from the average of a number of observations. The mean molecular weight of paranthracene calculated from ten sets of experiments comprising in all 118 separate readings was found to be 303, the lowest value observed being 248 and the highest 344. The measurements were made with an ordinary Beckmann apparatus, each degree of the thermometer being divided into 50 parts. The following table gives the results of a complete group of measurements:—

Paranthracene in the Solution per Cent.	Depression.	Molecular Weight (Molecular Depression for $C_{14}H_{10} = 701$).	Number of Trials.
0.059	0.012	344	7
0.108	0.023	329	7
0.132	0.027	342	7
0.146	0.037	276	8
0.229	0.053	303	10

For $C_{14}H_{10}$ the molecular weight is 178, and for $(C_{14}H_{10})_2$ 356, showing that paranthracene is formed from anthracene by the combination of 2 mols. According to Graebe and Liebermann, bromine has no action on paranthracene. The author, whilst confirming this observation, states that in the presence of sunlight, bromine strongly attacks para-

anthracene with formation of dibromanthracenetetrabromide. A similar result was obtained with anthracene when brominated under the same conditions.—D. B.

PATENT.

Improvements in the Distillation of Mineral Oils and Light Bodies, and in Apparatus therefor. J. Laing, Edinburgh. Eng. Pat. 6134, April 10, 1891.

THE chief improvement patented consists in making oil stills of such a form that the upper part only of the liquid in them is heated, and a sort of central well is provided into which the heavy residue can sink, and whence it can be drawn off periodically. The shape of the body of the still somewhat resembles the head of an ordinary still inverted, an annular fire playing on the wider part. The depth of the oil is maintained constant by means of a ball-cock or similar device. It is claimed that by this arrangement the heating is more uniform, and the distillation takes place at a lower temperature than in the ordinary form of still, while a smaller quantity of the oil is "cracked" and a better product is obtained.—B. B.

IV.—COLOURING MATTERS AND DYES.

Dyewood Extracts and their Manufacture. F. F. Mafat. Bull. Soc. Ind. Mulhouse, 1891, 361—452—(concluded). (This Journal, 1892, 154—155.)

THE appended tables show the composition (calculated to 30° B.) of the logwood extracts manufactured at Havre by the two methods already described (this Journal, 1892, 153—155).

Throughout the tables the weights given represent kilos.

LOGWOOD EXTRACTS, HAVRE (FIRST SYSTEM).

Brand.	Wood used.	Yield of Extract at 30° B.	Molasses at 30° B.	Chestnut Extract, at 30° B.	Carbonate of Soda.	Powdered Gypsum.
Logwood extract, dry, pure	1,000	1,000

—W. E. K.

Studies on the Colour-Derivatives of Triphenylmethane.
E. Noelting and Polonowsky. Bull. Soc. Ind. Mulhouse, 1892, 28—40.

The following *p*-amido compounds :

in addition to the *p*- and *m*-amido compounds previously mentioned (this Journal, 1890, 53, 279; 1891, 456), condense with tetramethyldiamidobenzhydrol (tetramethyldiamidodiphenylcarbinol). When the condensation is effected by means of sulphuric acid, leuco-compounds are obtained which melt at (1) 158°, (2) 142°, (3) 132°, and (4) 157°, and oxidise respectively into green, blue-green, green-blue, and blue-green dyes. Prehnidine (5) does not condense well. The authors have been unable to decide which of the two formulae—

represents the constitution of the compound obtained from α -*m*-xylylidine, but consider the second more probable, as symmetrical sulpho- and nitro-derivatives are obtained from that base. With mesidine, pseudocumidine, isoduridine, and prehnidine one formula in each case is alone possible.

When the condensation is effected by concentrated hydrochloric acid, the leuco-base from *m*-xylylidine melts at 145°; that from pseudocumidine at 163·4°. Both oxidise badly, in consequence probably of the combination taking place in the *o*-position to their amido-groups. The above-mentioned derivative of prehnidine also oxidises unsatisfactorily for the same reason. Mesidine and isoduridine yield with hydrochloric acid the same leuco-compounds as with sulphuric acid, but less readily.

The dibenzyl-compound obtained by treatment of hexamethyltriimidotriphenylmethane with benzyl chloride yields on oxidation a blue-green dye of sparing solubility. A

more soluble dye, suitable for wool and silk, is obtained by sulphonating the leuco-base before oxidising. As the ethyl-derivative of the compound—

yields on oxidation a green dye of yellower shade than the preceding, it would seem that the methyl-group in the *o*-position to the methane-carbon atom exercises a sensible influence on the shade of the resultant dye.

An isomeric dibenzyl-compound obtained by condensation of dibenzyl-*p*-toluidine and tetramethyldiamidobenzhydrol with sulphuric acid, oxidises to a dye of a pure green shade. In this case the methane-carbon atom is probably directly combined with the benzyl-group and not with the benzene nucleus, since benzylamine similarly yields the leuco-base of a green dye when condensed with tetramethyldiamidobenzhydrol.—E. B.

Sealed Notes deposited with the Industrial Society of Mulhouse by E. Noelting: opened October 28, 1891.
Bull. Soc. Ind. Mulhouse, 1892, 40—46.

Notes deposited April 2, 1887.

Note No. 499.—Diazoamidobenzoic acid—

when heated with aniline and aniline hydrochloride, undergoes a molecular interchange forming *amido-azobenzene carboxylic acid*—

The latter dyes yellow on cotton mordanted with alumina and olive on chrome. It may be diazotised and combined with aromatic amines, carboxylic acids, and phenols, yielding derivatives which dye cotton mordanted with metallic hydrates.

Note No. 500.—The hydrazine derivatives of carboxylic acids condense with ketones and diketones forming dyes. Thus dihydroxytartaric acid condenses with *m*-phenylhydrazine-carboxylic acid forming a hydrazone which differs from ordinary Tartrazine in its property of dyeing on alumina and chrome mordants. *o*- and *p*-phenylhydrazine carboxylic acids furnish similar condensation products. The hydrazine carboxylic acids also condense with phenanthraquinone and benzil, but the orange compounds obtained

are devoid of dyeing power. Balay, a student of Noebling's, finds that hydrazine-sulphonic acids condense with phenanthraquinone, forming valuable orange dyes suitable for wool.

Note No. 502.—Nitrotoluic acid—

[COOH:CH₃:NH₂ = 1:2:5] on fusion with soda, yields a compound which dyes unadorned cotton yellow. Reducing agents convert this compound into *diamidostilbene-dicarboxylic acid*, which can be diazotised and combined with phenols and amines, furnishing derivatives which dye unadorned cotton. The author considers it probable that all compounds which contain methyl- and nitro-groups in the *p*-position to each other, are capable of undergoing similar condensation and purposes further studying this reaction.—E. B.

PATENTS.

An Improved Process for Producing Azo-Colouring Matters. A. Fischesser, Lutterbach, Alsace, Germany. Eng. Pat. 3270, February 23, 1891.

In place of α - or β -naphthol used in producing insoluble azo-colouring matters on the fibre, it is proposed to employ β -hydroxynaphthoic acid having a melting point of 216° C. If dianisidine be diazotised and employed as the amine in this process, a blue is obtained resembling indigo, which resists soap and washing. The fibre is impregnated with the solution of the diazo- or tetrazo-compound and passed through an alkaline solution of the β -hydroxynaphthoic acid or *vice versa*. Passing the fibre through weak acid after dyeing is advantageous in developing the colour. If β -naphthylamine be employed it gives a Bordeaux, aniline a yellowish-red, nitraniline a fiery red, and tolidine a deep violet or reddish blue.—T. A. L.

Improvements in the Production and Separation of Methylamines, Ethylamines, Phenylamines, and Naphthylamines. R. Vidal, Paris, France. Eng. Pat. 3622, February 27, 1891.

The above amines are produced by the action of the hydroxy compounds or of the oxides of the hydrocarbon radicles upon nitrides of the metalloids, such as nitride of boron, cyanogen, and phosphane. An amine salt of an acid of the non-metal and an amine result, the change, in the case of phosphane, being represented by the following equations:—

With phospham and methyl or ethyl alcohol the reaction takes place at the ordinary pressure in a closed vessel at 230° C., 1 part of phospham to about 4 parts of the alcohol being employed. The resulting amine remains in solution in the excess of alcohol and can be readily separated.

Phenol and β -naphthol react at 300° C. with phosphane, but only under increased pressure, diphenylamine and β -dinaphthylamine being formed. The phospham is prepared by adding a solution of yellow phosphorus in carbon bisulphide to powdered sulphur, so as to moisten it, and heating the residue, after evaporating off the solvent, to a white heat with ammonium chloride. Boron nitride reacts less readily than phosphane; cyanogen and cyanides only yield traces of fatty or of aromatic amines.—C. A. K.

Improvements in the Manufacture of a Sulpho-Acid of Alpha-Naphthol, and of Colouring Matters therefrom. Read Holliday and Sons, Limited, T. Holliday and P. R. E. Seidler, Huddersfield. Eng. Pat. 5103, March 21, 1891.

If one part of α -naphthol be heated with 2½ parts of sulphuric acid of 66° B. at 100° to 140° F., until a sample on treatment with nitric acid gives little or no precipitate of dinitronaphthol, a new α -naphthol sulphonic acid is formed which can be precipitated from the melt by dilution with water and saturating the solution with salt. After filtration the salt of the new acid can be purified by recrystallisation from water. Another method of separating it from the mixture of α -naphthol sulphonic acids formed simultaneously is to fractionally precipitate them as azo-colours by the addition of diazoxylene or other diazo-compound. The new sulphonic acid forms the colour known as acid yellow when treated with nitric acid, and if a solution of the colour produced by combining diazotised naphthionic acid and an alkaline solution of the new naphthol sulphonic acid be spotted on paper the colour is unaffected by a 10 per cent. solution of sulphuric acid. The new acid is said to differ in these reactions from sulphonic acids of α -naphthol previously known, and is to be used for combination with diazo- and tetrazo-compounds for producing azo-colouring matters.—T. A. L.

Improvements in the Manufacture or Production of Ortho-orydiphenyl-carbon-acid. B. Wilcox, London. From F. von Heyden, Nachfolger, Radebeul, Germany. Eng. Pat. 5122, March 21, 1891.

ORTHO-HYDROXY-DIPHENYL, when dissolved in caustic soda, and the dry salt heated with carbon dioxide under pressure to 100—220° C., is converted into the corresponding carboxylic acid. The product of the reaction is dissolved in water and decomposed with hydrochloric acid when the free acid is precipitated, which melts at 180° C. It can be used as an antiseptic and for the manufacture of colouring matters and of dyestuffs.—C. A. K.

Improvements in the Production of Black Colouring Matters. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, und Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 5994, April 6, 1891.

By fusing the naphthol trisulphonic acid or the naphthosultone disulphonic acid described in German Patent 56,058 with caustic alkalis, a dihydroxynaphthalene disulphonic acid is formed, which will combine with two molecules either of the same or of different diazo-compounds. For example, one molecule of dihydroxynaphthalene disulphonate of soda is dissolved in water with four molecules of caustic soda to a 15—20 per cent. solution, and combined with a solution containing two molecules of diazobenzene chloride. After standing 12 hours the colouring matter is salted out. The most valuable colouring matters are those obtained by combination with diazo-compounds, one of which is sulphonated and the other not. Much deeper black shades can be produced by dyeing in an acid bath in the presence of chromates; the shades range from a blue to a greenish-black.—T. A. L.

Improvements in the Manufacture or Production of Azo-colouring Matters. B. Willecox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5984, April 7, 1891.

THIS is an extension of the following: Eng. Pat. 13,665 of 1889 (this Journal, 1890, 854, cf. Ger. Pat. 40,571), Eng. Pat. 3397 of 1890, Eng. Pat. 13,443 of 1890 (this Journal, 1891, 760), and Eng. Pat. 18,517 of 1889 (this Journal, 1890, 1032). All these patents refer to hydroxynaphthalene or naphthylamine sulphonic acids which have now been recognised as containing two hydroxyl groups, or a hydroxyl and an amido group in the 1:1' position. Several azo-colouring matters have already been described in the above specifications, and in addition, the following amines can be employed after diazotisation for combination with the sulphonic acids of 1:1' dihydroxynaphthalene and of 1:1' amidonaphthol.

1. Amido-phenols, amido cresols, and their substitution products which contain the amido and hydroxyl groups in other than an ortho-position.

2. The amidophenol ethers, amido-cresol ethers, amidonaphthol ethers, and their sulphonic acids, with the exception of those already described in Eng. Pat. 18,517 of 1889.

3. Nitraniline, amidoazobenzene, their homologues, and sulphonic acids.

4. Amidonaphthols, amidodihydroxynaphthalene ethers and their sulphonic acids.

5. Amidobenzoic acids and certain of their derivatives.

6. Phenylene, tolylene, and naphthylene diamines substituted in one of the amido groups by alkyl, phenyl, or benzyl and their sulphonic acids.

7. The amidoazo compounds formed by combining with α -naphthylamine or α -amidonaphthol ether the diazo-derivatives of the amines already mentioned under 2, 4, 5, and 6, and in addition the α - and β -naphthylamine trisulphonic acids. The colouring matters are dyestuffs for wool, giving mostly violet to blue shades.—T. A. L.

Production of Amidonaphtholsulpho Acids and of Dyestuffs therefrom. S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 6972, April 22, 1891.

AN extension of Eng. Pat. 16,699 of 1889 (this Journal, 1890, 935), Eng. Pat. 19,330 of 1890 (this Journal, 1891, 917), and Eng. Pat. 1742 of 1891 (this Journal, 1891, 918), which refer to the manufacture of azo dyestuffs derived from amidonaphthol sulphonic acids. Some new amidonaphthol sulphonic acids are described and also other processes for producing acids already known.

1. The acid II described in Eng. Pat. 1742 of 1891 can be obtained as follows: the naphthylamine trisulphonic acid obtained by nitration and reduction of the naphthalene trisulphonic acid of Eng. Pat. 15,716 of 1885 (this Journal, 1886, 662), when heated with caustic alkalis to 170°–190° yields after acidification an amidonaphthol disulphonic acid identical with acid II.

2. A new naphthalene trisulphonic acid is produced by sulphonating naphthalene β -disulphonic acid. This forms a mono-nitro derivative, which, on reduction yields a new naphthylamine trisulphonic acid of which the neutral sodium salt is easily soluble in water with a green fluorescence. If the acid be treated with caustic soda in an autoclave it is converted into a new amidonaphtholdisulphonic acid, of which the orange diazo-compound is turned blue by alkalis and can be precipitated by salt.

3. The naphthalene β -sulphonic acid gives a dinitro-derivative and on reduction forms diamidonaphthalene sulphonic acid, which is nearly insoluble in cold water. Heated with dilute mineral acids to 120° C. under pressure, it also is converted into a new amidonaphthol sulphonic acid nearly insoluble in cold water.

4. By sulphonating β -naphthylamine, the γ -disulphonic acid is not the only product formed. If, therefore, the crude melt be fused with caustic alkalis instead of the pure β -naphthylamine- γ -disulphonic acid, the γ -amido- β -naphthol sulphonic acid formed is somewhat altered as well as the

colouring matters therefrom. The colouring matter from tetrazodiphenyl (diamine black) becomes more violet.

5. By heating β -naphthylamine trisulphonic acid (corresponding to the known β -naphthol trisulphonic acid) with caustic alkalis according to Eng. Pat. 15,175 of 1889 (this Journal, 1890, 854), a β -amidonaphthol disulphonic acid is produced which can be used for the purposes of this invention. These amidonaphthol sulphonic acids are employed for the production of colouring matters as already mentioned in the previous patents. The specification also describes the preparation of new dyestuffs from colouring matters of which the acid II is one of the components. For instance, the colouring matter obtained from tetrazodiphenyl and amidonaphthol disulphonic acid II, which is a blue, can be diazotised and when combined with resorcinol gives a green which dyes unmordanted cotton. If α -naphthylamine be substituted for the resorcinol, a bluish black dyestuff results.—T. A. L.

Improvements in the Manufacture and Production of Dyes belonging to the Rhodamine Series, and of New Materials for Use in their Preparation. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 7258, April 27, 1891.

THE dyestuffs of the rhodamine series (Eng. Pat. 15,374 of 1887; this Journal, 1888, 745) cannot be converted into sulphonic acids by direct sulphonation. Certain benzylated m -amidophenol derivatives can be condensed with phthalic anhydride to yield new basic rhodamine dyestuffs, which on sulphonation yield sulphonic acids capable of employment as ordinary acid dyestuffs. Mono-methyl- or ethyl- m -sulphanilic acid is converted by the action of benzylchloride and caustic soda in an aqueous solution into methyl- or ethyl-benzyl- m -sulphanilic acid. This on fusion with caustic soda yields methyl- or ethyl- m -amido-phenol, which when heated with phthalic anhydride gives dimethyl- or diethyl-dibenzyl-rhodamine. The sulphonation is performed with fuming sulphuric acid, containing about 30 per cent. of sulphuric anhydride, and the sulphonic acid obtained dissolves to a fluorescent solution in hot or cold water, dyeing wool and silk from an acid bath in red shades fast to light and alkalis.—T. A. L.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Changes in Chromium Pigments. Papier Zeitung, 1891, 17, 292.

THE pigments used at present in paper staining are generally aniline-lakes obtained by precipitating the solutions of the various aniline dyes with solutions of sulphate of alumina and sodium carbonate.

The chrome yellows are obtained by precipitating a solution of lead acetate with a solution of bichromate of potash. Red and orange chromes can be produced by treating chrome yellow with caustic soda or potash.

Blanc fixe, which is used in the manufacture of "enamelled" papers, is the product of the precipitation of a solution of barium chloride with dilute sulphuric acid.

Generally speaking, the aniline lakes are very fugitive, more particularly so in direct sunlight. In paper staining they are mixed with blanc fixe, and those lakes produced from acid coal-tar colours give in these mixtures better results than the lakes from basic dyes. The glue which also forms part of these mixtures ought to be perfectly neutral.

The chrome yellows, which were always considered perfectly fast to light, according to the author, are quite unworthy of this reputation, and as a matter of fact are even more fugitive than the aniline lakes. Chrome

pigments precipitated upon the vegetable fibre are fairly fast, but their mixtures with aniline pigments and *blanc fixe* do not stand well at all.

The changes of the chromium pigments are due to the following causes:—

1. Insufficient agitation of the mixed pigments, causing the heavy chrome yellows to settle on the bottom of the vessel.
2. Mixture of yellow and basic orange chromes.
3. Too high a working temperature.

The decomposition of the glue with which the pigments are mixed may cause evolution of sulphuretted hydrogen which will very seriously affect the shade of the chrome yellow mixture.

Aniline pigments in similar mixtures are not liable to such changes.—C. O. W.

VII.—ACIDS, ALKALIS, AND SALTS.

The Solubility of Sodium Carbonate and of Sodium Bicarbonate in Solutions of Sodium Chloride. K. Reich. Monatsh. 1891, 12, 464—473.

THE method adopted by the author for the determination of the solubility of sodium carbonate in sodium chloride consisted in treating an excess of the deca-hydrated carbonate with solutions of sodium chloride of varying strengths at 15° C. in suitable flasks, the mixing being effected partly by shaking and partly in a rotating machine worked by a water motor. After the mixing by hand the contents of the flasks were allowed to stand overnight, and the final mixing in the rotating machine given the following morning for 1—2 hours. Variations in the time of mixing between these limits were found to give concordant results. The solutions were then filtered and the filtrates titrated with decinormal silver nitrate and with seminormal hydrochloric acid to determine the sodium chloride and the sodium carbonate respectively.

In the following table *x* and *y* are the number of parts of sodium chloride and of sodium carbonate respectively dissolved by 100 parts of water:—

<i>x</i> , (NaCl)	<i>y</i> , (Na ₂ CO ₃ ·10 H ₂ O) Observed.	<i>y</i> , (Na ₂ CO ₃ ·10 H ₂ O) Calculated.	Difference.
0·00	61·12	61·41	+0·01
4·03	53·86	53·88	—0·02
8·02	48·00	48·05	—0·05
12·02	43·78	43·77	+0·01
16·05	40·96	40·91	+0·05
19·82	39·16	39·15	+0·01
23·70	39·06	39·06	0·00
27·93	39·75	39·81	—0·08
31·65	41·11	41·37	+0·07
35·46	43·77	43·78	—0·01
37·19	45·22	45·10	+0·12
37·27	45·32	45·16	+0·16

In the two last experiments a mixture of sodium chloride and sodium carbonate was treated with a quantity of water insufficient to dissolve either constituent, in which case it is seen that the solubility of both salts increases somewhat as compared with the calculated result. This calculated value is obtained from the first 10 of the above observations by the method of least squares for a parabolic curve of the third order, corresponding to the equation—

$$y = 61·406 - 2·091077x + 0·055493x^2 - 0·000297357x^3$$

The results show that the solubility of sodium carbonate in sodium chloride solutions decreases with an increase in the quantity of sodium chloride present at first, and then increases and therefore there must be a certain strength of sodium chloride solution in which the solubility of sodium carbonate is a minimum. This minimum value calculated from the above equation is with $x(\text{NaCl}) = 23·15$.

$$y(\text{Na}_2\text{CO}_3 \cdot 10 \text{H}_2\text{O}) = 39·05.$$

From the above equation the solubility of anhydrous sodium carbonate in sodium chloride can be calculated, the resulting equation being—

$$y_1 = 16·4082 - 0·70749x_1 + 0·0166143x_1^2 + 0·00010258x_1^3$$

in which x_1 and y_1 represent the proportions of sodium chloride and of sodium carbonate respectively contained in

100 parts of the solution. From this the following numerical values result:—

x_1 (NaCl)	y_1 (Na_2CO_3) Observed.	y_1 (Na_2CO_3) Calculated.	Difference.
Per Cent. 0.00	16.42	16.408	+0.012
2.92	14.47	14.476	-0.006
5.80	12.87	12.833	-0.043
8.61	11.62	11.614	+0.006
11.31	10.70	10.680	+0.020
13.71	10.11	10.096	+0.014
15.98	9.76	9.764	-0.004
18.26	9.62	9.653	-0.033
20.06	9.73	9.730	0.000
21.75	9.95	9.935	+0.015
22.45	10.12	10.060	+0.060
22.48	10.13	10.064	+0.066

The minimum solubility in this case corresponds to—

$$x_1(\text{NaCl}) = 18.22$$

$$y_1(\text{Na}_2\text{CO}_3) = 9.65$$

The following table gives the solubility of the anhydrous carbonate in sodium chloride solutions of various percentage strengths:—

x_1 NaCl	Na_2CO_3	x_1 NaCl	Na_2CO_3
Per Cent.		Per Cent.	
0	16.408	12	10.488
1	15.717	13	10.244
2	15.060	14	10.041
3	14.438	15	9.880
4	13.851	16	9.762
5	13.299	17	9.686
6	12.783	18	9.655
7	12.305	19	9.667
8	11.864	20	9.725
9	11.461	21	9.828
10	11.097	22	9.977
11	10.773		

The determination of the solubility of sodium bicarbonate in sodium chloride solutions was determined by passing carbon dioxide into saturated solutions of sodium carbonate in sodium chloride at 15° C. Solutions of sodium chloride of various strengths were employed in which so much sodium carbonate was dissolved that a small quantity of bicarbonate was precipitated after passing in the carbon dioxide, the latter being passed until the solution ceased to colour turmeric paper. The resulting solution was then rotated as described, at 15° C., and the sodium chloride and sodium bicarbonate determined volumetrically after filtration. No allowance was made for the slight increase of pressure due to the liberation of carbon dioxide in the shaking; 0.2 parts of carbonic acid were allowed for as being taken up by every 100 parts of solution. The results thus obtained go to show that the quantity of bicarbonate precipitated from solutions of sodium carbonate in sodium chloride by carbon dioxide at 15° increases with an increase in the strength of the original sodium chloride solution.

The following numerical values have been calculated from the results obtained:—

Per Cent. NaCl in the original Solution.	Na_2CO_3 in 100 parts of this Solution.	NaHCO_3 left in Solution after passing in CO_2	Precipitated NaHCO_3	Per Cent. of Na_2CO_3 of precipitated as NaHCO_3
10.642	10.884	2.968	14.252	82.62
15.804	9.782	1.869	13.634	87.95
15.932	9.768	1.847	13.635	88.07
21.618	9.915	1.061	14.053	93.25
23.71	10.31	0.886	15.504	94.6

The last result is obtained from the curve for the solubility of anhydrous sodium carbonate in sodium chloride solutions.
—C. A. K.

On the Decomposition of Sodium Nitrate by Sulphuric Acid. C. W. Volney. J. Amer. Chem. Soc. 1891, 13, 246—251.

When distilling nitric acid from the usual mixture of sodium nitrate and sulphuric acid it is frequently observed that at certain periods a violent reaction sets in, and that the contents of the retort are carried over into the receivers. The general supposition is that overheating is the cause of this. The author here distils a mixture of 2,500 grms. of sodium nitrate and 2,600 grms. of commercial sulphuric acid (sp. gr. 1.837 at 67° F.) in a glass retort having a capacity of about two gallons, and heated in a bath of paraffin; temperature of the bath and the temperature of the evolved products were noted. The results obtained show that the products of distillation pass over in three distinct fractions, and that the frothing commences with the beginning of each part of the reaction preceding distillation of the various strengths of nitric acid, although the temperature of the bath did not greatly exceed the temperature of the distilling products. The first fraction passing over showed the temperature 77°—90° C. and weighed 960 grms.; its specific gravity was 1.5193 at 60° F., and in colour it was almost white; the second fraction showed the temperature 94°—109°, weighed 565 grms., had a sp. gr. 1.505, and was very faintly yellow; the third fraction showed the temperature 117°—122°, weighed 316 grms., had a specific gravity of 1.42, and was of a light yellow colour. The author considers the reactions best explained by the existence of several hydrates of nitric acid; the sodium nitrate is not completely decomposed by sulphuric acid at a low temperature, and the decomposition takes place in stages, frothing occurring as each stage is suddenly reached.—T. L. B.

The Nitrate Fields of Chili. C. M. Aikman. Blackwood's Mag. March 1892, 1—9.

THE chief deposits at present being worked are those lying in the Pampa of Tamarugal, in the province of Tarapaca. They stretch at a distance of thirty or forty miles inland, from Pisagua southwards to somewhat beyond the town of Iquique. This huge desert, as has been already indicated, seems to be entirely destitute of all vegetation and animal life. Even in the immediately adjoining country the only kind of vegetation that seems to grow is a species of *acacia*. The few streams that are found in this neighbourhood are entirely fed by the melting snow from the Cordilleras. Darwin describes the appearance presented by these pampas as resembling "a country after snow, before the last dirty patches are thawed."

Scattered over the pampas, at various distances from one another, are situated the *oficinas*, or nitrate manufactories, where the raw material is refined. Seen from a distance, their most conspicuous features are their tall black chimneys. According to Dr. Russell, they present a general resemblance

to gas works, with the adjuncts of a coal-mine. Nearer approach shows them to consist of a cluster of buildings, with open boiling-pans, liquor-vats, and machinery of different kinds. There is something very striking in the presence of these *oficinas*, so indicative of life and enterprise in the midst of sandy deserts, and dependent for everything on external supplies brought from a great distance. Of these manufactories there are a considerable number in different parts of the pampas. Many of them are old, and not in work. Most of those in active work at present are the property of foreigners; and two-thirds of the nitrate exported from Chili is said to come from *oficinas* owned by English companies. Beside the *oficina* are the houses of the manager and his staff, and the huts of the native workmen. Every *oficina* possesses a public store, or *pulperia*, where the employes obtain their provisions. The whole group of buildings constitutes what is called a *maquina*. The extent of the property of each manufactory naturally varies, but some of the largest estates extend over 12 square miles.

The *caliche*, or raw nitrate of soda, is not equally distributed over the pampas. The most abundant deposits are situated on the slopes of the hills which probably formed the shores of the old lagoons. An expert can tell, from the external appearance of the ground, where the richest deposits are likely to be found. The *caliche* itself is not found on the surface of the plain, but is covered up by two layers. The uppermost, known technically as *chuca*, is of a friable nature, and consists of sand and gypsum; while the lower—the *costra*—is a rocky conglomerate of clay, gravel, and fragments of felspar. The *caliche* varies in thickness from a few inches to 10 or 12 feet, and rests on a soft stratum of earth called *coca*. The mode in which the *caliche* is excavated is as follows: A hole is bored through the *chuca*, *costra*, and *caliche* layers till the *coca* or soft earth is reached below. It is then enlarged until it is wide enough to admit of a small boy being let down, who scrapes away the earth below the *caliche* so as to form a little hollow cup. Into this a charge of gunpowder is introduced, and subsequently exploded. The *caliche* is then separated by means of picks from the overlying *costra*, and carried to the refinery. Both in appearance and composition it varies very much. In colour it may be snow-white, sulphur, lemon, orange, violet, blue, and sometimes brown like raw sugar. The *caliche* found in the Pampa de Tamarugal contains generally about 30 to 50 per cent. pure nitrate of soda; that in the province of Atacama contains from 25 to 40 per cent. The subsequent refining processes, which consist in crushing it by means of rollers, and then dissolving it, need not here be described. It may be sufficient to mention that the process used is that known as systematic lixiviation, and is analogous to the method introduced by Shanks in the manufacture of soda. The chief impurity in the raw material is common salt; gypsum, sulphates of potassium, sodium, and magnesium, along with insoluble matters, are the other impurities. The manufacture of iodine, which, as has been already noticed, is found in the nitrate beds, is also carried on at these *oficinas*.

Formerly the refined article had to be carried to the coast on mules; now, however, there is railway communication, which maintains a constant and ever-increasing traffic with Iquique, Pisagua, and the other nitrate ports. Of these, Iquique is by far the most important. In respect of its situation and surroundings, this little town is one of the most striking in the world. The following is Darwin's description of it when the "Beagle" visited it in 1835:—

"The town contains about 1,000 inhabitants, and stands in a little plain of sand at the foot of a great wall of rock 2,000 feet high, here forming coast. The whole is utterly a desert. A light shower of rain falls only once in very many years; the ravines are consequently covered with detritus, and the mountain sides covered with piles of white sand, even to a height of 1,000 feet. During July a heavy bank of cloud stretches over the ocean; it seldom rises above these walls of rocks on the coast. The aspect of the coast is most gloomy. The little port, with its few houses, seemed overwhelmed and out of all proportion with the rest of the scene. The inhabitants live like persons on board

of ship. Every necessary is brought from a distance; water is brought in boats from Pisagua, about 40 miles by water, and is sold at the rate of 4s. 6d. an 18-gallon cask. Very few animals can be maintained in such a place. I hired with difficulty, at the high price of 4l., two mules and a guide to take me to the nitrate of soda works." Since 1835, however, the appearance of the town has changed very much for the better. The enormous development of the nitrate trade has effected a corresponding development in Iquique. Its population is now between 16,000 and 20,000, very largely consisting of foreigners; and the town can boast of a fairly imposing appearance. Much of its food supplies has still to be brought from a distance, but the town now possesses a water supply of its own. The example of a town of this size so dependent on external sources is indeed unique.

The question of the extent of the nitrate of soda deposits is naturally one of very great interest, especially from the agricultural point of view.

Lefrange, a French writer, estimated a few years ago that they still contained about 100,000,000 tons of pure nitrate of soda. Opinions on this point differ very considerably, and it seems wellnigh impossible to arrive at any very accurate estimate. The number of years they will last will depend, of course, on the amount of annual exportation. This, at present, falls little short of 1,000,000 tons. If this amount is maintained they should last, according to experts, some twenty or thirty years at least.

Hitherto the Government of Chili has been content to allow foreign enterprise to open up the nitrate fields, imposing a heavy tax on all nitrate manufactured. The enormous source of revenue which nitrate of soda is to the Chilean Government may be inferred from the fact that one *oficina* alone pays about 750l. per diem, or in round numbers 250,000l. per annum, of export duty on the nitrate there manufactured.

PATENTS.

Improvements in the Preparation of Chlorine. G. E. Davis and A. R. Davis, Manchester. Eng. Pat. 6416, April 28, 1890. (Reprint.)

THE claims embodied in the original patent (this Journal, 1891, 463) are abandoned, with the exception of the second claim for "the utilisation of the water charged with impurities from the wash tower D for preserving the normal strength of the nitric acid employed in the operation . . ."

—H. A.

Improvements in the Manufacture of Chlorine. G. E. Davis and A. R. Davis, Manchester. Eng. Pat. 6698, May 1, 1890. (Reprint.)

THE claims of the original patent (this Journal, 546, 1891) are restricted to "the process of manufacturing chloronitrous gas by acting upon an aqueous solution of hydrochloric acid with nitrosulphuric acid in the presence of air in a tower packed with suitable material . . ."

Improvements in Apparatus for the Condensation of Nitric Acid. E. Edwards, London. From O. Guttman and L. Rohrmann, Krauschwitz, Germany. Eng. Pat. 10,629, June 22, 1891.

The inventors find it important in the condensation of nitric acid "that the nitric acid as formed should be brought out of contact with the impurities contained in the gases as quickly as possible." This is effected by a double connexion of the still with the receivers. A series of top-connexions, consisting of upright pipes and bends, enables the gases to pass from receiver to receiver, whilst an inclined main connected with the bottom of each receiver makes possible the drawing off of the condensed acid as it is formed. To prevent the gases from the still or the receivers from entering this main, the latter is divided into chambers by means of partitions or diaphragms between each receiver inlet, which chambers communicate through elbows luted with acid (this Journal, 1890, 862).—H. A.

X.—METALLURGY.

The Melting Points of the Gold Aluminium Series of Alloys. W. C. Roberts-Austen. Roy. Soc. Proc. 1892, 50, 367—368.

By means of the Le Chatelier thermo-couple the author has found that, although a white alloy of gold and aluminium containing 10 per cent. of the latter has a melting point 417°C . below that of gold, yet the purple alloy AuAl_2 has a melting point 32.5°C . higher than gold. Alloys containing more aluminium have melting points which fall continuously to 660°C . The author points out that the purple alloy is the only known case of an alloy, free from mercury, having a higher melting point than that of the least fusible of its constituents, and that this affords strong

evidence of its being a true compound of gold and aluminium.—J. C. C.

The Molecular Changes of Iron. H. Morcillon. Bull. Soc. Ind. de Mulhouse, 1891, 629—656.

THE author has examined the effect of various thermal and mechanical conditions upon a specimen of wrought iron having a tensile strength of 38 kilos. per sq. mm.* and an elongation on 200 mm. of 26 per cent.

(1.) *Effect of Temperature.*—The effect of heating iron having a fibrous structure is to give rise to a crystalline granular condition, the result being more noticeable the higher the temperature and the more its influence is prolonged. Quenching in water does not modify the granular state produced by the heating. By annealing at a temperature below that to which the iron has been subjected in order to change its fibrous structure to a crystalline one its original condition is to a great extent restored.

(2.) *Effects of Mechanical Work.*—The general effect of working in the cold is to lead to the production of a granular structure and to cause a partial separation along the lines of welding. In extreme cases the extension diminishes to a mere fraction of its normal amount, and although the tensile strength is considerably raised, the material becomes brittle and unreliable.

(3.) *Effect of Annealing.*—By annealing at suitable temperatures the fibrous character can be restored to iron which has assumed a crystalline condition from one or other of the causes mentioned above.

The molecular alteration indicated by the appearance of the fracture has a considerable influence on the mechanical properties of the iron. The alteration from the fibrous to the crystalline state is generally accompanied by a diminution in tensile strength, while the elastic limit is but slightly altered and the elongation is decreased. Although a red heat appears to be necessary to bring about the changes recorded above, yet considerable alterations in the mechanical properties of iron and steel take place at lower temperatures, as has been shown by A. le Chatelier (*Genie Civil*, 147, 107; cf. this Journal, 1889, 710). In all cases in his experiments the tensile strength decreased from a temperature of 15°C . up to 80°C . above which it rose again and attained a maximum at 250° — 300°C . These results are shown more clearly in the diagram below.

* (To convert kilos. per sq. mm. into tons per sq. in. multiply by 0.06364.)

A difference is observed according to the speed with which the test is made, the dotted lines uniformly following a different course from the continuous lines which represent the figures obtained by the slower tests. The elastic limit appears to decrease in proportion as the temperature is

increased. The diminution is very slight at first, but beyond 300° C. it becomes extremely rapid and difficult to measure. The effect upon the elongation is shown by the diagram below.

It is noticeable that if a test piece be heated to a moderate temperature, *e.g.*, 100° C., and then slightly stretched, it will be found to give a higher tensile strength when tested afterwards at the ordinary temperature than one which has not been thus treated. The elastic limit is also raised and the elongation decreased. The following table shows some figures obtained in this way:—

SWEDISH IRON.

Tested at 15° C.	Tested at 15° C. after being stretched 3 per Cent. at 150° C.
Tensile strength, 30.9 kilos. per sq. mm.	38.14 kilos. per sq. mm.
Elongation, 25 per cent.	15 per cent., including the original 3 per cent.

VERY MILD STEEL (SAINT CHAMOND).

Tested at 15° C.	Tested at 15° C. after being stretched 3.5 per Cent. at 220° C.
Tensile strength, 36.18 kilos. per sq. mm.	40.45 kilos. per sq. mm.
Elongation, 25 per cent.	12.5 per cent., including the original 3.5 per cent.
Elastic limit, 24.6 kilos. per sq. mm.	39.5 kilos. per sq. mm.

The practical deductions from these facts as to the probable changes that may occur in iron worked at a slightly elevated temperature are sufficiently obvious, especially when it is considered that these temperatures are those frequently attained by boiler plates. The phenomenon in question is not confined to the temperature mentioned, as at the ordinary temperature repeated strains on a test piece are known to raise the elastic limit by successive increments without affecting the ultimate tensile strength. Thus in a series of tests made by H. Deschamps (Revue Universelle des Mines et de la Métallurgie, November 1890) the following results were obtained with a steel which when tested in the ordinary way had an elastic limit of 30.3 and a tensile strength of 55.7 kilos. per sq. mm.

		Kilos. per Sq. mm.
Experiment (1) ...	Elastic limit.....	30.4
	Tensile strength.....	31.3
Experiment (2) ...	2nd elastic limit.....	35.3
	Final tension.....	39.3
Experiment (3) ...	3rd elastic limit.....	40.3
	Final tension.....	41.4
Experiment (4) ...	4th elastic limit.....	45.3
	Final tension.....	49.2
Experiment (5) ...	5th elastic limit.....	49.2
	Final tension.....	53.2
Experiment (6) ...	6th elastic limit.....	53.2
	Final tension.....	55.5

Metal which has suffered such a change as is here indicated, having its elastic limit approximating to its ultimate tensile strength, is obviously a very dangerous material.

The foregoing results refer to iron which has been subjected to physical changes only, its ultimate chemical composition having been left unaltered. Deep-seated alterations of structure are also brought about by variations in composition. For example, a specimen of "burnt" iron with a coarse crystalline structure and extremely cold-short taken from the hearth of a welding furnace contained 0.764 per cent. of phosphorus with 0.139 per cent. of silicon and a trace of carbon, while the original iron before "burning" had taken place contained at most 0.2 per cent. of phosphorus, the increment being due to contact with the slag from the molten portion. It has been contended that the fibrous or granular structure of iron is primarily dependent on the manner in which fracture has been effected. This is to a certain extent true, but does not invalidate experiments in which the method of fracture is kept identical in all cases where comparisons have to be made.

With regard to the influence of the impurities usually present in iron on the grain of the metal, carbon makes the structure closer and finer, approximating eventually to that of steel, while silicon within ordinary limits (say up to

0·15 per cent.) has but little effect; phosphorus renders the grain coarse and more crystalline, and sulphur has no very marked influence. Manganese is not commonly present in appreciable amount in ordinary puddled irons.—B. B.

On the Possibility of Extracting the Precious Metals from Sea-Water. C. A. Münster. (Norsk Tekniak Tidsskrift, Kristiania, 10th Vol., No. 1., February 29, 1892.)

THE author recounts the experiments of Malaguti, Durocher and Sarzeand, estimating the amount of silver present in sea-water, and the later ones of Sonstadt, proving the presence of gold. After pointing out several possible sources of error in the various processes adopted he describes the method used by himself. Sea-water was taken from Kristiania Fjord, and 100 litres were evaporated to dryness, giving 1,830 grms. of residue. This was ground, and divided into portions of 300 grms., each of which was mixed with 100 grms. of litharge, 100 grms. of pure KNaCO_3 , and four grms. of carbon from starch, and the silver and gold determined.

The result was,—19 mgrms. silver and 6 mgrms. gold per ton of average sea-water.

By check experiment this result was modified to a final result, the effect of which was that one ton of average sea-water contains 20 mgrms. of silver and 5 mgrms. of gold per ton, worth respectively 0·03 and 0·19 of a penny.

Considering the extremely small amounts of precious metals present, the author considers that no method of precipitation in tanks can possibly be successful, instancing the failure of H. Munktel, who tried precipitation with protosulphate of iron and milk of lime, at Bømmelø, on the west coast of Norway. He thinks that the precipitation must be effected in the sea itself, where the water is continuously renewed by a natural current, and points out that the copper sheathing of vessels has long been known to precipitate silver under these circumstances, estimating that at least one gm. is precipitated per annum on each square metre of surface exposed.

He proposes that a channel about 60 metres wide between two small islands, well sheltered from sea or wind, where there is a current of about 4 metres per minute, should be selected for the experiment, such rocky islets being common off the Norwegian coast; across this channel, 60 plates of galvanised iron each 2 metres \times 3 metres, should be arranged at an angle of 30° to the stream, and an electric current be sent through the series to precipitate the precious metals. The power required theoretically for this purpose he calculates at only $\frac{1}{2}$ H.P., and thinks that to produce a current of such trivial potential difference in practice would only require a few horse-power, which could cheaply be obtained from water-power, wind, or even by the thermo-electric principle utilising the difference of temperature between the sea and the air. The large anodes required could be cheaply prepared from wood, impregnated with graphite and tar, and carbonised, high conductive power not being required for such a feeble current. If all the precious metals passing these plates were precipitated, he calculates that over 300,000l. would be obtained per annum, and as the working expenses would be most trivial, if only $\frac{1}{1000}$ th or even $\frac{1}{10000}$ th of this amount were obtained, it would still pay well; he therefore thinks the experiment well worth a trial.—J. H. C.

PATENTS.

Improved Method or Process for Treating Metal-bearing Bodies, and the Recovery of Metals therefrom. W. C. Loe, London. Eng. Pat. 5937, April 18, 1890.

FREE milling matrices are pulverised to float and calcined with one-fortieth part of potassium hydrate and one-eighth part of sulphur to a dull red heat for 2—4 hours. The product is then washed in tanks at 200° (F. 2°), and the liquor drawn off at the top. The latter is then treated with a saturated solution of calcium sulphide, when a black slime is precipitated. This is roasted and the residue fluxed and

refined by known means. If necessary, the potash and sulphur may be brought into solution by boiling with water before being added to the ore. The sulphur may be omitted if the ore contain sufficient of that element. Complex ores are first mixed with a saturated solution of ferrous sulphate, dried and roasted, and are then treated with potash and sulphur. If the ore contain less than $2\frac{1}{2}$ per cent. of iron sufficient oxide of iron must be added to make up the deficiency.—H. K. T.

An Improved Method for Treating Cupreous Liquors for the Purpose of utilising the same. C. Höpfner, Giessen, Germany. Eng. Pat. 18,080, November 10, 1890.

THIS patent consists of precipitation processes for extracting copper and other metals from crude copper solutions derived from the roasting and lixiviation of copper pyrites and from other sources.

The copper solution is first converted into a mixture of cupric chloride and sodium sulphate by the addition of either sodium chloride or copper sulphate, and the copper is then precipitated as cuprous chloride by treating the liquor with metallic copper, silver being precipitated as metal at the same time. The solution now contains only sodium sulphate together with traces of iron, nickel, &c. The latter are precipitated by known processes, and the liquor then treated for the separation of Glauber's salt. If the original liquor is acid, it is first neutralised by the addition of cuprous or cupric oxide. Cuprous sulphide, oxide, or carbonate can be used instead of metallic copper for precipitating copper from the cupric chloride solution. In this case iron, manganese, and other metals are also precipitated. The necessary cuprous oxide is obtained by treating cuprous chloride with caustic lime. The copper precipitate, which may contain metallic copper, cuprous and cupric oxides, and cuprous chloride, is next dissolved in a neutral or alkaline solution of some chloride which will dissolve cuprous chloride, such as sodium, potassium, cupric or magnesium chloride, when silver, bismuth, arsenic, and antimony are left behind as metal or oxidised compound. Metallic copper is obtained in a state of purity from the solution by electrolysis. Other methods of extracting the copper from the cuprous precipitate are to treat it with lime and utilise the oxides which are produced. Or the cuprous oxide precipitate may be heated with sulphuric acid, when metallic copper and cupric sulphate are obtained. Reduction by iron can also be used. As the oxidation and chlorination of pyrites by roasting is often incomplete, it is advisable to separate magnetic pyrites from the roasted mass by means of magnets before leaching, and to submit these pyrites to a separate treatment.—H. K. T.

Improvements in Apparatus for and Process of Treating Zinc Ores. W. West, Denver, Colorado, U.S.A. Eng. Pat. January 20, 1891.

THIS is a process for the reduction of ores occurring in America, consisting of a mixture of sulphides of zinc, lead, iron, and copper, together with some gold and silver, and has especial reference to the economical extraction of the zinc. The process consists in roasting the ore so as to obtain sulphurous anhydride, and then allowing this gas, after it has been cooled to a temperature below 180° F., to act upon a moist and previously roasted portion of the ore, thereby forming soluble sulphite of zinc. The latter is then dissolved out with water, the zinc precipitated as hydrate with ammonia and reduced in the usual way. The ammonia is recovered by distilling the liquor from the above precipitation with lime and the extracted ore is treated by the usual methods for the remaining metals. The apparatus used in the process consists of a roasting chamber heated from below, a zig-zag flue which conveys the hot sulphurous anhydride, and which is covered with iron plates to form a floor on which previously extracted ore can be dried; thus effecting at one and the same time the drying of the ore and the cooling of the gas, further cooling apparatus if necessary, a blower to exhaust the gas from the roasting chamber and force it into the leaching vessel, a pipe conveying steam

which mixes with the gas before it enters the leaching tank and furnishes the necessary moisture and a leaching vessel provided with a false bottom on which the ore is supported. The chief novelty of the process consists in the use of a mixture of sulphurous anhydride gas and steam instead of a solution of the gas in water, whereby the bulk of liquid to be treated is greatly reduced and the production of sulphuric acid, and consequent solution of copper and iron, avoided.

—H. K. T.

Improved Gold Extracting Reagents. J. H. Poilok, Glasgow. Eng. Pat. 1309, January 24, 1891.

This patent is for improvements in the chemicals used in the processes described in Eng. Pats. 17,495 of 1887, 16,796 of 1888, and 5578 and 10,298 of 1889 (this Journal, 1890, 444, &c.) A small proportion of sodium sulphite is now melted in with the nitre cake to remove any trace of nitric acid, any increase of acid desirable being obtained by adding sulphuric acid to the nitre cake before the addition of the sulphite. Also instead of using crystallised ferrous sulphate to precipitate the gold, the crystals are first broken and then raised in a steam-heated vessel furnished with agitators to any desired temperature. By raising the temperature from 100° C. to 150° C. the salt is left with only one molecule of water, and is therefore lighter and costs less for transport.

—E. T.

Treating Ores and Residues containing Zinc by Means of Bisulphate of Soda for the Production of Commercial Products. A. M. Clark, London. From F. E. Costes, "La Société Anonyme de Produits Chimiques, Etablissements Malétra," Paris, France. Eng. Pat. 1374, January 24, 1891.

ACCORDING to the present invention, zinc turnings, filings, and other scrap, scum and dross from molten zinc, galvanisation residues, slimes from the washing of calamines and blendes, calamines or blendes too poor in zinc for distillation, and other waste products containing zinc, are utilised by treatment with the waste residues from the manufacture of nitric acid, known as bisulphate of soda. The zinc waste is mixed with a variable proportion of bisulphate of soda according to its richness in zinc (thus zinc ashes containing 70 per cent. of zinc would require $2\frac{1}{2}$ or 3 times their weight of bisulphate), introduced into a reverberatory furnace with refractory lining, and the charge withdrawn immediately the mass becomes pasty and homogeneous, and after nearly all the vapours have ceased to disengage. The zincic frit obtained is thrown into water, which dissolves the sulphates of zinc, sodium, and iron, leaving the gangue and impurities in the residue. The solution is decanted off, and after separating the iron by any suitable means, the sulphate of soda is crystallised out and prepared for the market. The zinc in the mother-liquors is then precipitated either by lime-water, sodium sulphide, or ammonia, and the precipitate of oxide or sulphide of zinc calcined in a muffle furnace, the temperature in case of the sulphide being kept below 400°–500° C. The product is a zinc white, which has a good colour, is unctuous, and covers well.

If metallic zinc is required, the oxide or sulphide should be well washed, moulded into bricks, and highly calcined; the product is an oxide containing 70 per cent. of zinc, which on reduction distils over in one-half less time than that required by ordinary calcined calamines.

If ammonia is used for precipitating the zinc, the sulphate of ammonia is crystallised out from the mother-liquors, but if lime-water or sulphide of sodium have been used, the mother-liquors may be utilised for the manufacture of barium sulphate or "blanc fixe" by adding to them a weak solution of barium hydrate of low quality, and collecting the precipitate.—S. B. A. A.

Improvements in the Treatment of Composite Ores containing Zinc. P. Hart, Manchester. Eng. Pat. February 4, 1891.

This process is intended for poor ores of a composite nature in which the metals exist as sulphides or partly as sulphides and partly as oxides. The ore is finely powdered, mixed with sulphuric acid of sp. gr. 1.750 and heated to 300° to 400° F., gases consisting chiefly of sulphurous anhydride are given off and are conducted into a sulphuric acid chamber and converted into sulphuric acid. The mass is next gradually heated to redness to render iron salts insoluble and is then lixiviated. Copper is removed from the solution by means of zinc and the solution of zinc sulphate is then evaporated and crystallised or used for any purpose for which it is suitable. Any lead which the ore may contain will be found as sulphate in the residue and may be extracted by means of a strong solution of brine or other solvent, the metal being separated from the solution by electrolysis or other means. Or the magna of silica, lead sulphate, &c. may be smelted in the ordinary manner. No apparatus other than that used in the manufacture of sodium sulphate is required.—H. K. T.

A Process for the Extraction of Tin from Tin Slags and Tin Refuse by Lead or its Salts, Carbonaceous Matter, Fluorspar, or other suitable Fluxes. F. H. Mason, London. Eng. Pat. 10,985, June 27, 1891.

TIN slag or refuse from tin-smelting is crushed so that the largest pieces do not exceed the size of a walnut, and mixed with 15 per cent. of fluorspar or other suitable flux, a quantity of lead ashes or salts of lead containing three times as much lead as there is tin in the slags, and sufficient anthracite to reduce both the lead and tin compounds. The mixture is charged into a reverberatory or low blast furnace, and the temperature raised until the mass melts. The whole is then kept at a uniform heat and well rabbled until the bubbling ceases; a little anthracite is then thrown in, and the rabbling continued until the mass is again quiet; the metal is then run out and cast into ingots. These ingots are next subjected to a process of liquation, the portions first liquating out being collected apart; the other portions are heated and poled, the product being an alloy of tin and lead which may be utilised as solder.—S. B. A. A.

Improvements in Blast Furnace Linings. J. T. King, Liverpool. From J. Gayly, Braddock, U.S.A. Eng. Pat. 13,690, August 14, 1891.

THE brickwork lining of the boshes and hearths of a blast furnace generally undergoes rapid corrosion until, owing to certain reactions, a carbonaceous deposit is formed on these parts, which to some extent arrests the destructive action. This coating, however, is liable to be removed by slags of exceptional composition. The inventor, therefore, proposes to line the walls of the boshes with graphitic bricks composed preferably of 75 parts of fireclay and 25 parts of graphite set in a mortar of the same material, and forming a layer of 18 in. or less in depth. The bricks are tempered, moulded, and burnt in the usual manner, no sensible deterioration being caused by the last operation; the proportions of the ingredients may be varied, other forms of carbon substituted for graphite, and 20 per cent. or less of lime or 5 per cent. or less of magnesia may be added to render the bricks more refractory and durable.

—S. B. A. A.

Improvements in Apparatus for Leaching Ores in separating Gold and Silver therefrom. W. D. Bohm, Chiswick. Eng. Pat. 14,737, September 1, 1891.

IN treating certain ores by forcing a leaching solution upwards through them and then through a filter at the upper part of the vat, the filter is liable to become clogged and the working impeded. According to the present invention this is obviated by the use of a vat provided with a filter both at the top and bottom with corresponding

openings, the vat being arranged so as to turn on trunnions when required, and reverse the position of the filters. The bearings contain passages through which the liquid is forced into and passes from the vat, and which communicate with the openings at the ends of the vat, the connexions being reversed when the vat is turned. For the mechanical details of the construction of the vat and attached gearing the drawings and description in the specification must be consulted.—S. B. A. A.

Improvements in Blast Furnace Linings. J. Johnson, Liverpool. From J. Gayly, Braddock, U.S.A. Eng. Pat. 19,330, November 9, 1891.

THE inventor proposes to line the boshes and hearth of blast furnaces with bricks composed of coke and tar for the purposes explained in the preceding abstract (Eng. Pat. 13,690, of 1891). The bricks are prepared as follows: Good hard coke of graphitic appearance and low in ash is ground in a pug mill, heated, thoroughly incorporated with 5 to 15 per cent. of hot tar according to the pressure obtainable at the moulding machine, moulded into bricks and fired at a low temperature in a muffle furnace. Anthracite coke and charcoal may be used in addition to ordinary coke in the manufacture of the bricks. The latter are generally arranged as a lining to the boshes and hearth, but in iron jacketed furnaces, they may form the whole thickness of the wall in those regions.—S. B. A. A.

Improvements in the Treatment of Ores. A. M. Clark, London. From C. G. Richardson, W. D. Firstbrook, Toronto, and E. H. Davis, Montreal, Canada. Eng. Pat. 20,521, November 25, 1891.

ACCORDING to this invention ores containing sulphides, arsenides, or sulpharsenides are freed from sulphur and arsenic by treatment with steam. The ore is pulverised, placed in a closed receptacle which is kept in a state of constant agitation and may be heated or otherwise, and superheated or other steam is passed in until the ore contains no more sulphur and arsenic than is desirable. The bases remain as oxides; the sulphur and arsenic may be recovered by collecting the sulphuretted and arseniuretted hydrogen evolved and treating these gases in any suitable manner.

—S. B. A. A.

An Improved Method of Treating Plumbiferous Copper Mattes and Ores. C. James, Swansea. Eng. Pat. 22,041, December 16, 1891.

THE process described is an improvement on the method of Eng. Pat. 13,739 of 1891 (this Journal, 1891, 1012), and deals with the same classes of material. According to the improved process the matte is crushed, completely calcined, preferably in a revolving calciner, mixed with *raw matte*, and silica or siliceous ore or other matter in such proportions as to provide sufficient sulphur to combine with all the copper present and sufficient silica to form a silicate of iron and lead; the mixture is then melted in a reverberatory furnace. If the proportion of silica be so adjusted as to be quite neutralised by the lead and iron present the products will be a rich regulus or coarse copper entirely free from lead, and a lead slag nearly free from copper. Any silver or gold originally present in the matte is almost entirely concentrated in the copper regulus.

Ores containing more than 15 per cent. of lead cannot be completely calcined, and are best reserved for admixture with calcined ores of lower lead content. For example, 8 parts of a thoroughly calcined matte containing 36 per cent. of copper and 16 per cent. of lead mixed with 3 parts of a raw matte containing 32 per cent. of copper and 24 per cent. of lead, yielded on fusion a coarse copper with 90 per cent. copper free from lead and a slag containing 19 per cent. of lead. Deoxidation of the matte during fusion, as in the "roaster" process, or by addition of oxidising agents, with the simultaneous introduction of silica, is also claimed.—S. B. A. A.

Improved Material for making Amalgam for Filling Teeth and Method of Manufacturing the same. G. Jüterbock, Berlin, Germany. Eng. Pat. 22,211, December 19, 1891.

FOR the purpose of filling teeth, dentists dissolve an alloy of silver and tin in mercury, and, if required, add a certain proportion of gold or platinum. The alloy is supplied in filings or chips which are contaminated with dirt and small particles of metal from the cutting tool, and are, moreover, liable to oxidation. This is remedied according to the present invention by rolling the alloy into sheets, which are electro-plated with gold and cut into pieces. The layer of gold protects the alloy from oxidation, but at once dissolves in mercury, exposing the pure alloy, which is rapidly amalgamated.—S. B. A. A.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

PATENTS.

Improvements in Means for Use in Electrolysis. J. Marx, Frankfurt-on-Main, Germany. Eng. Pat. 6266, April 24, 1890. (Second Edition.)

THE apparatus described is especially suited to the electrolysis of such solutions as that of sodium chloride, where the materials resulting from electrolysis at one electrode must, as far as possible, be kept apart from those set free at the other. For this purpose the liquid is always employed in a shallow layer with pointed anodes dipping a short way into it, while the cathodes, placed alongside, are covered by hoods to catch the hydrogen liberated. No diaphragms are employed.—E. T.

Improvements in Electro-depositing. W. Gibbings, Garston. Eng. Pat. 2518, February 12, 1891.

A BEAM of insulating material is placed on each side of the tank, below the surface of the electrolyte. The plates are supported by projections at the top which rest at each side on the beams. Current is led in and out by the end plates, but as all the plates are insulated from each other, except through the electrolyte, it is as though a number of cells had been formed, each plate acting as a division wall and being a cathode to one cell and anode to the next. By placing the supporting beams sufficiently low down, the plates may be wholly immersed and waste in that way prevented.—E. T.

Improvements in and Apparatus for Electrolysing and Bleaching. J. Marx, Bad-Nauheim, Germany. Eng. Pat. 3738, March 2, 1891.

IN the electrolysis of sodium chloride by such apparatus as that described in Eng. Pat. 6266 of 1890 (see above), it is impossible to prevent a certain amount of recombination between the chlorine and the alkali liberated. The patentee diminishes this by treating the electrolysed solution with carbon dioxide so as to leave alkaline carbonates or bicarbonates and hypochlorous acid. The liquor is then again electrolysed, perhaps with the addition of more chloride, and the acid present prevents so much of this recombination taking place. If a bleaching solution is desired, the recombination is rather favoured, and a larger amount of carbonic dioxide used, so as to produce more hypochlorous acid, which acts as a bleaching agent. To absorb the carbonic acid, the liquor is allowed to flow down an inclined plane furnished with ridges in an atmosphere of the gas.—E. T.

Improvements in the Electric Reduction of Aluminium and other Metals, and in the Production of Alloys therefor. T. L. Willson, Brooklyn, U.S.A. Eng. Pat. 4757, March 17, 1891.

A CRUCIBLE of carbon is made the anode while a carbon rod, introduced through a non-conducting lid, serves as cathode. The current consequently passes upwards through the ore in the crucible, to the negative electrode above. To prevent wasting of either electrode, powdered carbon or coal, &c. are fed in. For aluminium bronzes, copper is fed in with the ore. With iron ore and corundum an aluminium steel can be made.—E. T.

Improvements in the Formation of Ozone in Presence of Air or Oxygen, and Apparatus therefor. A. Schneller and W. J. Wisse, The Hague, Holland. Eng. Pat. 5222, March 21, 1891.

THE ozonising chamber contains a number of electrodes enclosed in tubes of glass or other good di-electric material. These electrodes are alternately + and -, but as they are joined up to a transformer or alternating current dynamo giving a large E.M.F., their polarity is perpetually changing. Drawings are also given of apparatus for freeing the air or oxygen of dust and moisture before passing it into the ozonising chamber.—E. T.

Improvements in Electric Batteries. H. I. Harris, London, and W. H. Power, Anerley. Eng. Pat. 5918, April 6, 1891.

THE invention consists in the use of iron and sulphur cells as the electrodes of a battery, and water as the exciting fluid. The sulphur cell is insulated from the iron, and they are closed by a water-tight lid. The water is led in at the bottom of the outer cell, percolates under pressure through the brimstone, and is siphoned off from the inner cell. The supply can be regulated by a tap.—G. H. R.

Improvements in Galvanic Batteries. S. Marcus, L. Patz, and R. Grebner, Vienna, Austria. Eng. Pat. 6243, April 11, 1891.

THE invention consists in making one of the electrodes of cylindrical shape, the other being placed within it in the form of a triangle, square, or other suitable prism, so that the two electrodes come into close proximity at certain points, whilst between these points hollow spaces are left for the electrolyte.—G. H. R.

Improvements in Automatic Regulating Apparatus employed in connexion with Galvanic Batteries. J. Y. Johnson, London. From F. Gendron, Bordeaux, France. Eng. Pat. 6247, April 11, 1891.

ACCORDING to this invention, which is specially applicable to two fluid cells, the several vessels containing the liquids are arranged in a frame having three stages with insulating rollers, on which the vessels can be readily moved. The two upper shelves carry the battery cells, while the tanks containing the liquids are placed on a lower one. A small motor driven by a current from the battery works the two circulating pumps, which may be of any suitable construction, but are preferably "Sansay pumps," specially designed for acid liquids. One pump is used for the exciting liquid, and the other for the depolariser. Each pump is connected with the corresponding store tanks by branch pipes provided with stop-cocks and valves worked automatically by sliding rods, so arranged that when one set of valves is open the other is shut. The sliding rod is provided with ratchet-shaped teeth, and is capable of being moved laterally by an electro-magnet so as to bring the lateral projections into the path of one or other of the legs of a forked lever, to which the motor imparts a continuous vibrating motion. By engaging with this lever the rod is caused to work the valves and place the pump

in connexion with the different tanks. Similar mechanism controls the number of cells in action at one time, and puts them in or cuts them out as required.—G. H. R.

Improvements in Electrical Accumulators or Storage Batteries. C. P. Elieson, London. Eng. Pat. 7697, May 4, 1891.

THIS invention consists in building up the electrodes of a series of corrugated envelopes of cylindrical or other desirable shape, composed of thin lead or other suitable metal, and preferably perforated. These envelopes are placed one within the other, and the corrugations are so arranged that those of one cylinder cross, or are at an angle, to those of adjacent cylinders. Suitable means are provided for preventing them coming into contact.—G. H. R.

Improvements in Electrodes for Electric Accumulators. W. P. Thompson, Liverpool. From H. O. Tudor, Rosport, Luxembourg. Eng. Pat. 8227, May 13, 1891.

THE improvements consist in forming the electrodes of a plate, the two surfaces of which are provided with grooves or ridges of any suitable form or depth, instead of the plain plate mentioned by the inventor in Eng. Pat. 11,543 of 1887; and these grooves or ridges have on each side of them other smaller grooves, running horizontally or vertically as previously described.—G. H. R.

Improvements in Galvanic Batteries. R. Haddan, London. From I. Cabanyes, Paris, France. Eng. Pat. 8845, May 25, 1891.

THE improved cell is constructed as follows:—the outer case is composed of two cases of wood placed one within the other, the space between being filled with melted paraffin. The carbon electrode is composed of a number of carbon rods fixed to a copper connecting ring. A suitable number, preferably four of these, are connected to form one electrode. The zinc rods dip into porous jars placed within each group of carbons, and are so arranged that any one may be removed and replaced while the battery is working. The solution for the carbons in the outer case or jar consists of a mixture of equal parts of nitric acid and hydrochloric acid, to which mixture is added water acidulated with 5 per cent. of sulphuric acid. The volume of water is equal to the volume of the two acids together.—G. H. R.

A Process and Apparatus for Increasing the Bleaching Properties of Chlorine Gas. C. Kellner, Manchester. Eng. Pat. 22,438, December 23, 1891.

THE chlorine is treated in the same way as air when it is desired to produce ozone. Two pieces of apparatus are described. The first consists of two test tubes, one inside the other, and fused together at the top. The chlorine passes, by a tube at the bottom of the outer test tube, into the space between the two, and passes out near the top. The inner tube contains sulphuric acid as one electrode, while more sulphuric acid, in which the outer tube is immersed, serves as the other electrode. In the other apparatus the gas passes by a zigzag course between flat vessels, alternately + and -, containing sulphuric acid. The polarity is rapidly changed in the usual way.—E. T.

Improvements in and relating to Secondary Batteries. J. B. Entz and W. A. Phillips, Bridgeport, Conn., U.S.A. Eng. Pat. 1484, January 26, 1892.

THE object of the invention is to render the electrolytic action more uniform over the surface of the plates during charge and discharge, thus securing longer life to the cell. This is effected by heating the bottom of the cells, thus causing the liquid to circulate.—G. H. R.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

The Glycerin and Artificial Butter Industry under United States Patents. E. Starek. School of Mines Quarterly, 1892, 13, 131—141.

ONE of the earliest commercial methods for the manufacture of glycerin is that of saponifying fats by means of lime and distilling off the glycerin with superheated steam; it however necessitates the use of sulphuric or oxalic acid to neutralise any free alkali and to decompose the lime soaps for the recovery of the fatty acids. No early American patent appears to have been issued for such a process, but lime is used in conjunction with superheated steam by Werk (U.S. Pat. 1858, 21,711); and, later, oxides of zinc and tin, "chloride of lime," and a mixture of zinc oxide and lime is used to effect the saponification and separation of the fatty acids from glycerin and water by Litzelman (this Journal, 1883, 43), Max Ams and Litzelman (U.S. Pat. 1883, 272,510), and Banjard (U.S. Pat. 1883, 280,894). Glycerin is, however, obtained on a large scale by the decomposition of fats with superheated steam, and from the sub-lye of the soap maker. Tilghman (U.S. Pat. 1854, 11,766) devised an apparatus whereby fat or oil in a fluid state is emulsified with water, and the emulsion passed through a coil of iron tubing heated to the temperature of melting lead, and then through a cooling coil heated to 212° F., from which it escapes into the receiving vessel. Wright and Fouché (U.S. Pat. 1859, 22,765) constructed an apparatus in which the decomposition is effected by the continuous circulation of highly-heated water in a finely-divided state through the fats; and since then forms of apparatus have been devised whereby the fats are thoroughly atomised by the steam while they are undergoing decomposition. (See Sahfeld (U.S. Pat. 1878, 201,704), Kuehne (U.S. Pat. 1879, 215,372), Babbitt (U.S. Pat. 1883, 275,976; 1885, 316,104).)

Clovis (U.S. Pat. 1881, 242,272) recovers glycerin from soap lyes by neutralising the same with hydrochloric acid; Battershall (this Journal, 1883, 91) neutralises with sulphuric acid; whilst Domeier and Hagemann (U.S. Pat. 1887, 371,127) precipitate the soapy matters as insoluble soaps, and subsequently concentrate the lye, the remaining fatty and resinous constituents being decomposed by hydrochloric acid, and mechanically removed with clay or alumina. The manufacture of resin soap simultaneously with that of glycerin is covered by the last-mentioned patentees (U.S. Pat. 1888, 385,105); whilst Mitting (U.S. Pat. 1888, 385,367) precipitates the fatty and resinous impurities by the addition of barium or strontium chloride, and the latest attempts have been directed towards preventing the mechanical occlusion of glycerin by the salts, this

APPARATUS FOR THE MANUFACTURE OF GLYCERIN.

being effected by the apparatus of Domeier and Hagemann (U.S. Pat. 1890, 428,468). A is the boiler in which the concentration is effected, B the enclosing brickwork, C the fire space, D the metal outer wall, E and F girders, G the receptacle for the precipitated salts; it can be separated from A by closing the valve H. G¹ is a door through which the collected matter is removed, G² a strainer or perforated plate. Soap-lye or brine containing less glycerin than that adhering to the mineral crystals can be admitted through G³, the deposits remaining on the strainer G², whilst the liquid escapes by G¹. At the commencement of the operation, A is filled with soap-lye, and as it is in communication with G, the latter is also filled; when the boiling liquor in A becomes more concentrated the precipitates formed pass into G. The apparatus is fed through G⁴, the liquor contained in G being thus pushed into the boiling portion. As soon as G is filled with deposited crystals, H is closed, the excess of liquor removed through G⁵, and the crystals washed as described, and removed. H is now opened and the process repeated.

Some manufacturers precipitate the soap by an excess of alkali, which is then removed by treatment with more fat (Babbitt, U.S. Pat. 1870, 107,324), or by treatment with carbonic acid, which converts the alkali into bicarbonate insoluble in glycerin (Mellen, U.S. Pat. 1890, 422,140). Hydrate of iron is employed for the last mentioned purpose by Domeier and Hagemann (U.S. Pat. 1892, 453,829).

The concluding portion of the paper deals with artificial butter, and mentions some 10 American patents for its production, extending from 1873—1882.—A. R. L.

The Composition of Turkey-Red Oil. P. Juillard. Bull. Soc. Chim. 1891, 6, 638—656.

IT is well known that the product of the action of monohydrated sulphuric acid on castor oil, after removal of the excess of acid by washing with a solution of an alkaline salt, consists essentially of two portions, one of which is soluble, the other insoluble, in pure water. According to Liechti and Suida (this Journal, 1883, 540) the soluble portion has the constitution $(C_{11}H_{21}O_5 \cdot C_3H_5 \cdot OH)_2SO_4$. Müller-Jacobs (this Journal, 1884, 412), on the other hand, looks upon it as a sulphonic acid of ricinic acid; while Benedikt and Ulzer (this Journal, 1888, 329) consider it to be a ricinosulphuric ester of the formula $H_8O_4 \cdot C_{17}H_{32} \cdot COOH$. The portion insoluble in water is, in the opinion of Liechti and Suida, dihydroxyricinic acid; in that of Müller-Jacobs, Benedikt, and others, a mixture of ricinic acid and unaltered ricinolein.

The author has shown (Arch. de Genève, 1890, 24, 134 and 1891, 25, 275; see also this Journal, 1891, 171) that, in spite of its inaccuracy, the formula of Liechti and Suida gives a molecular weight closely approaching that of the soluble portion obtained by washing in the cold; and that the formula proposed by Benedikt and Ulzer represents the actual state in the molecule of the sulphuric acid residue, though it is much too simple to express the constitution of the chief soluble compound produced, since, as the author has discovered, polymerisation of the fatty acids is accomplished simultaneously with their esterification by the action of sulphuric acid.

Ricinic Acid, $HO \cdot C_{17}H_{32} \cdot COOH$, contains an alcoholic hydroxyl group, by reason of which it is capable of readily yielding ethers; thus with acetic acid it yields an acid ester of the formula $C_2H_3O_2 \cdot C_{17}H_{32} \cdot COOH$; with oleic acid, similarly, an oleoricinic acid $C_{18}H_{34}O_2 \cdot C_{17}H_{32} \cdot COOH$; and with ricinic acid, ricinoricinic or diricinic acid—

The last-named compound contains a hydroxyl group which enables it to condense with another molecule of ricinic acid, forming tricinic acid, which in turn is condensable with 1 mol. of ricinic acid, yielding tetrarinic acid, and with two, yielding pentarinic acid. These poly-ricinic acids may be produced from ricinic acid by the

action of hydrochloric acid, their formation probably taking place in two stages, thus—

With sulphuric acid a similar series of changes takes place—

and so on, to the formation of pentaricinic acid. In this case, however, the intermediate compounds have been isolated and examined.

The immediate action of sulphuric acid on castor oil is to produce a diricinoleinsulphuric anhydride of the formula—

according to the equation—

The formation of this body being presumably preceded by that of diricinoleinsulphuric acid—

This anhydride in contact with ricinic and sulphuric acids then slowly undergoes change into polyricinosulphuric and polyricinic acids.

Properties of the Polyricinic Acids.—The portion of Turkey-red oil which is insoluble in water and which usually amounts to about one-third of the whole, consists of a mixture of ricinolein (when, as is generally the case, the oil is prepared from castor oil and not from ricinic acid), and mono- and polyricinic acids. Its quantity may be increased by prolonging the duration of the washing of the acid oil; after several months' contact with water, the sulphuric acid residue being completely eliminated from the acid magma. Polyricinic acids are further producible by keeping the washed Turkey-red oil at a temperature of 20°–30° for several weeks, as well as by the action of hydrochloric acid on ricinolein or ricinic acid at the ordinary temperature or more rapidly (in 2–3 hours) at 95°–100°. They were first obtained in a fairly pure state by the author by fractional separation from commercial Turkey-red oil which had undergone spontaneous decomposition. The latter appeared as a viscid liquid, soluble in ether, light petroleum, and benzene, imperfectly in acetic acid, and sparingly so in cold, but easily so in hot alcohol; its molecular weight, determined by Raoult's method (phenol being used as solvent and the lowering of solidifying point being compared with that produced by aceticricinic acid) was 994. On the addition of alcohol to the ethereal solution of this oil a voluminous, oily precipitate was obtained which, after being washed several times with alcohol, had a molecular weight corresponding with that of *pentaricinic acid*. The ethereal-alcoholic mother-liquor, after the evaporation of the ether, deposited an oil which was washed with concentrated alcohol and submitted to analysis, giving numbers corresponding with those required for *triricinic acid*. The alcoholic solution from which the latter compound had separated, was cooled to 0° and a precipitate

obtained which was purified with warm alcohol, the residue then showing a molecular weight of 592 approaching that of *diricinic acid* (578).

Penta- and tetraricinic acids are viscid oils; are completely insoluble in cold, concentrated alcohol; sparingly soluble in acetic acid; freely so in ether, light petroleum, and benzene; their alkaline salts are difficultly soluble in dilute alcohol. Submitted to prolonged treatment with hydrochloric acid, they do not undergo further condensation; suspended in alcohol and treated with dry hydrochloric acid gas, they are slowly transformed into ethyl ricinate. In common with the other polyricinic acids, they are undecomposed by boiling solutions of alkaline carbonates, but are converted by boiling solutions of caustic alkalis into salts of monoricinic acid. *Triricinic acid* is soluble in ether, light petroleum, acetic acid, and excess of alcohol; its alkaline salts in dilute alcohol. *Diricinic acid* is soluble in all proportions in light petroleum, ether, acetic acid, and absolute alcohol; its alkaline compounds are insoluble in water, but soluble in dilute alcohol; on titration with normal potash solution and phenolphthalein it absorbs a smaller quantity of alkali than it theoretically should.

Properties of the Polyricinosulphuric Acids.—A mixture of the various polyricinosulphuric acids is readily obtained by precipitating with common salt an aqueous solution of washed Turkey-red oil, after removal of the portion extractible with ether by treatment with that menstruum. This mixture, after the spontaneous evaporation of the ether, which it retains in small amount, appears as a viscid, yellow oil; is hydrated; soluble in all proportions in water, alcohol, and ether; and in aqueous solution readily dissolves ricinic acid and ricinolein, and less readily the polyricinic acids. It is decomposed by boiling water, or more rapidly by boiling dilute acids into fatty acids, glycerin, and sulphuric acid. This portion of the Turkey-red oil constitutes about two-thirds of the total oil-magma, and consists chiefly (three-fourths or so) of diricinoleinsulphuric anhydride, as is proved by its high neutralising equivalent; thus in two experiments 2.24 and 2.82 per cent. of KOH were respectively required, while diricinoleinsulphuric acid, which has approximately the same molecular weight, requires 9.39 per cent. Left some time at the ordinary temperature in the presence of a slight excess of caustic potash, the anhydride is converted into diricinoleinsulphuric acid. The latter compound is very unstable; when liberated by a mineral acid from its alkaline salts, it decomposes almost instantly into monoricinosulphuric acid, ricinic acid, and glycerin. The anhydride in an aqueous solution, to which a small quantity of mineral acid has been added, suffers a similar change, but is quite stable in solution in excess of pure water. In concentrated aqueous solution, however, it gradually decomposes successively into polyricinosulphuric and polyricinic acids. The anhydride is further decomposed by boiling solutions of caustic alkalis and of alkaline carbonates in excess into monoricinosulphuric acid, ricinic acid, glycerin, and an alkaline sulphate; if normal potash solution be added in successive small doses to a solution of the anhydride whilst being heated for a period of 18 hours, there is required to neutralise 12 to 16 times the amount required in the cold. Boiling alcoholic potash decomposes the anhydride almost completely into monoricinosulphuric acid and ricinic acid, a trace only of potassium sulphate being produced. This greater resistance of potassium monoricinosulphate towards alcoholic than towards aqueous potash, the author considers to be probably due to the production in the former case of a salt containing two atoms of potassium, which is stable in the presence of excess of alkali.

In the author's opinion the diricinesulphuric acid described by Scheurer-Kestner (this Journal, 1891, 471) is not a uniform substance, but a mixture of that acid with diricinoleinsulphuric anhydride, monoricinosulphuric acid, and fatty acids insoluble in pure water, which a single treatment with ether is insufficient to remove from aqueous solution.

Composition of Turkey-red Oil.—The Turkey-red oils of commerce vary considerably in composition. As a general rule, however, they consist of a mixture of diricinoleinsulphuric anhydride and of the alkaline (sodium or am-

monium) salts of diricinoleinsulphuric, mono- and polyricinoleinsulphuric, and of mono- and polyricinic acids, along with unaltered ricinolein.

Analysis of Turkey-red Oil.—In addition to the usual estimation of the fatty acids, the glycerin and sulphuric acid should be determined, the latter by precipitation as barium salt, after decomposing the oil-mixture by boiling with hydrochloric acid. In view also of the different shades yielded in dyeing and printing by the various components of the oil, a determination of the molecular weight of the fatty acids present in the soluble and insoluble state, is desirable. This may be accomplished by Raoult's method, but care must be taken, when decomposing the soluble portion, that a sufficient amount of water is used to bring the whole of it into solution, otherwise the results obtained are too high. The author condemns the method of testing Turkey-red oil suggested by Scheurer-Kestner (this Journal, 1891, 471) in which the soluble and insoluble portions of the oil are directly estimated by titration with standard ammonia, litmus and phenolphthalein being successively employed as indicators. This method gives inaccurate results, especially when diricinoleinsulphuric anhydride is present in the oil, which is almost invariably the case.—E. B.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

On the Manufacture of Chrome Pigments. C. O. Weber. Dingl. Polyt. J. 1891, 282, 138, 183, and 206.

Chrome Greens from Chrome Yellows.—It has become customary to apply the term of chrome green not only to chromic hydrate (Guignet's green) and other compounds of chromic oxides, but also to the green pigments which represent mixtures of chrome yellow and Prussian blue.

The quality of these mixed chrome greens depends upon—

- (a) the nature of the chrome yellow used,
- (b) the nature of the Prussian blue used,
- (c) the process of producing the mixture of the two.

Only those chrome yellows possessing a pure lemon colour will produce bright greens, but the brightness of the green has very little to do with the brightness of the yellow, provided the latter is only free from even the slightest touch of orange, which always tends to produce shades known as olive-greens or moss-greens.

Lemon shades of chrome yellow are generally obtained by the simultaneous precipitation of lead sulphate and lead chromate, and it might appear that the proportion of sulphate and chromate contained in such a yellow would be a matter of indifference so long as the proper shade of chrome yellow was obtained, and this is certainly so as far as only the shade of the resulting chrome greens is concerned. But on a closer investigation of this matter we find that the proportion of sulphate contained in a chrome yellow stands in the inverse ratio to the covering power of the green obtained from it. This makes it desirable to keep the proportion of lead sulphate in chrome yellows intended for chrome greens as low as possible, and very

seldom we find in a chrome yellow for green the proportions of lead sulphate and lead chromate to be more than 2·5 of the former to 5 of the latter.

The following formulae yield chrome yellows of this description which are well adapted for the manufacture of chrome greens:—

I.

36 lead acetate (or 32 lead nitrate),
7·5 potassium bichromate,
7·5 sulphate of alumina,
5 carbonate of lime (Paris white).

The solution of the lead salt is precipitated with the united solutions of the bichromate and the sulphate of alumina to which the lime carbonate has been added.

II.

26 acetate of lead,
7·5 potassium bichromate,
3·5 Glauber's salt crystallised,

or—

III.

36 acetate of lead,
7·5 potassium bichromate,
7·8 Glauber's salt, calculated,
9 soda ash.

After precipitation the yellows are washed once or twice by decantation, and in the interest of the beauty of the product this ought to be done in the least possible space of time. The chrome yellows are thus obtained in the form of a thin paste to which the Prussian blue, also in paste, is added, the quantities of course depending entirely upon the required shade of green. After well agitating the mixture of yellow and blue the green is pressed and dried. This process of manufacturing chrome greens is very old, but it is still largely practised. The process is, however, a very unsatisfactory one, as it is difficult to always produce a desired shade of green and it involves also a waste of Prussian blue, as the latter even when in a paste cannot be brought in such a state of fine subdivision as to be capable of producing its maximum effect. Very remarkable is the great fugitiveness of greens prepared in this manner, an hour of exposure to direct sunlight often being sufficient to destroy the shade of the green, turning it a dirty-looking yellow. This bleaching is accompanied by evolution of considerable quantities of cyanogen and proceeds independently of the presence of oxygen, nor is it in the least retarded by exposing the green in vacuo or in an atmosphere of pure oxygen, ozonised oxygen, hydrogen, nitrogen, or carbonic acid. On treating such a bleached green with dilute nitric acid, ferric oxide and chromic oxide are found in solution, but no lead, the latter probably being converted into peroxide, thus:—

Considerably faster greens are obtained by adding the well-diluted paste of Prussian blue to the solution of the lead salt before precipitation, but this method is no more economical as regards the use of Prussian blue than the former.

The function of lead sulphate in chrome yellows has been exhaustively treated in a former article (this Journal, 1891, 709—712), but attempts to produce chrome yellows suitable for the manufacture of chrome greens free from sulphate of lead were frequently made. The first practicable process was originated about 12 years ago, and consists in the precipitation of a solution of lead acetate with a solution of bichromate of potash partially reduced by acetic or citric acid. 20 lb. of bichromate are dissolved in 6 gallons of boiling water and 2 lb. of powdered citric acid added. A violent reaction ensues, and eventually a dark olive-brown solution is obtained, with which a solution of 56 lb. of lead acetate in 100 gallons of water is precipitated. The resulting chrome yellow possesses a dull, very greenish shade, and produces with Prussian blue exceedingly bright and strong shades of chrome green. As the result of a

careful analytical investigation of this process the reaction between potassium bichromate and citric acid was found to proceed according to the equation—

This equation, verified by experiment and analysis, shows that, not as might have been expected, the whole of the citric acid is oxidised, but that about 30 per cent. of the total quantity is converted into chromium citrate, so that on precipitation of the lead salt with the above chromate mixture a small quantity of lead citrate is simultaneously precipitated; and further experiments revealed the fact, that this small quantity of citrate prevents the "turning" of the shade of the "lemon chrome" obtained. Careful observation of the following rules will entirely prevent the turning of chrome yellows:—

1. The yellow must be precipitated in the presence of excess of lead salt.

2. Simultaneously with the chromate of lead must be precipitated the lead salt of an acid easily oxidisable by chromic acid. This lead salt must be insoluble in the free acid forming on precipitation of the chromate.

3. If such lead salts are used the free acid of which would dissolve the lead salts of the oxidisable acids, the precipitation must be performed by means of mono-chromates.

That the "turning" of the chrome yellows is due to a decomposition of the lead chromate into a basic salt, whereby chromic acid is set free, the slightest traces of which have a most detrimental influence upon the beauty of the shade, is now an established fact. The cure for the tendency of the chrome yellows to decompose in this manner is the presence of a small quantity of the lead salt of an easily oxidisable organic acid, which also prevents the rapid destruction (oxidation) of chrome greens, a process which, as shown above, is also an oxidation process.

Chrome Yellows for Chrome Greens.—For the manufacture of chrome yellows for chrome greens ferrocyanhydric acid or its soluble salts are very suitable, as, owing to the insolubility of ferrocyanide of lead in dilute nitric acid, they allow of the production of these pigments from nitrate of lead.

The method of manufacturing chrome greens by adding the Prussian blue paste to the solution of the lead salt before precipitation, or by adding it to the already formed chrome yellow, has been shown above to be uneconomical and there is no doubt that the best and most economical form in which the Prussian blue can be used is that of a solution. As is well known, Prussian blue may be dissolved in certain acids or salts, and these solutions are most advantageously employed in the manufacture of chrome greens. Oxalic acid has been used for this purpose by Vogel, who dissolves the Prussian blue in 10 per cent. of its weight of oxalic acid, then adds a solution of bichromate of potash and subsequently precipitates with this mixture a solution of lead acetate. The following proportions have been employed by Vogel:—

- 20 Prussian blue,
- 2 oxalic acid,
- 40 potassium bichromate,
- 100 lead acetate.

It will be noticed that the chrome yellow contained in this green is also free from sulphuric acid, and the beauty and fastness of the green so obtained must be ascribed to the presence in it of a small quantity of lead oxalate. In adding the solution of bichromate to the solution of Prussian blue containing the oxalic acid a very violent reaction takes place, but there is no doubt that it proceeds on the same line as the one between bichromate and citric acid, and accordingly comes to a standstill as soon as all free oxalic acid has disappeared, partly through oxidation, partly through formation of chromium oxalate. In perfect agreement with this assumption is the observation that neutral oxalates are not oxidised by solutions of bichromate, either hot or cold.

There is a large number of other substances capable of dissolving Prussian blue, but as a rule they are more expensive than oxalic acid, especially so considering that oxalic acid not only acts as a solvent for the blue, but is also essential in producing full and fast shades of chrome yellow.

The capability of potassium ferrocyanide to dissolve Prussian blue is also utilised in the manufacture of chrome greens. But whereas oxalic acid easily dissolves dry Prussian blue, ferrocyanide of potassium dissolves this pigment satisfactorily only in the form of a paste. The quantity of ferrocyanide used is best about 20 per cent. of the weight of the Prussian blue which is to be dissolved, a few minutes' boiling being sufficient to produce a dark blue solution which may be filtered without leaving any residue on the filter. On addition of indifferent salts, such as Glauber's salt, to such solutions, the blue is apparently precipitated as it settles from the solutions, but on stirring it up the apparent precipitate can be filtered through filter-paper almost as completely as the original solution. On addition of a solution of bichromate to the solution of the blue, the former of course acts at once with great energy on the ferrocyanide contained in the latter, and the blue apparently is precipitated, although the mixture filters without any residue. By precipitating with this mixture a solution of lead acetate or nitrate, greens are obtained which in beauty rival brilliant green lakes, and owing to the ideal state of sub-division of the blue, the latter is enabled to produce in every case its maximum effect. The following proportions may serve as an example:—

V.

- 300 Prussian blue (4 per cent. dry),
- 2.4 ferrocyanide of potash,
- 18 potassium bichromate,
- 50 lead acetate.

This corresponds to the following proportions according to Vogel's method:—

VI.

- 300 Prussian blue (4 per cent. dry),
- 2 oxalic acid,
- 18 potassium bichromate,
- 50 lead acetate.

These two greens, although practically identical in regard to their chemical composition, differ very much in their appearance, which no doubt is due to the difference in the amount of bichromate reduced in the course of the two processes respectively. The result obtained in working according to the proportions VI. may be considerably improved upon by using oxalate of ammonia instead of oxalic acid for the solution of the Prussian blue:—

VII.

- 300 Prussian blue (4 per cent. dry),
- 3 oxalate of ammonia,
- 18 potassium bichromate,
- 50 lead acetate.

The shade of this green is brighter than that of chrome green VI., and at the same time very much bluer than even that of chrome green V., and this shows that by using oxalate of ammonia even less blue is necessary for the production of a certain shade than by using either oxalic acid or ferrocyanide. Moreover, green VII. is distinguished by its truly remarkable fastness. This latter method might be used on a large scale with considerable advantage.

A combination of the above-described oxalate and ferrocyanide processes has been in use for some time in this country and in America, and the chrome greens obtained by the combination of these two methods are remarkable for the delicacy and purity of shades, as well as for their great fastness to light. It is not easy to see why chrome greens obtained by the combined methods should be at all superior to those produced by either of the two methods. Considering, however, that oxalic acid and potassium ferrocyanide act at boiling temperature not only upon the Prussian blue, but also upon each other, and that ferric oxide, which is invariably produced by the action of oxalic

acid on Prussian blue, is eventually re-converted into blue through the ferrocyanide present, the *rationale* of this method is explained to a considerable degree. The following formulæ are types of this method:—

	a.	b.	c.
Lead acetate.....	100	100	100
Litharge	50	50	50
Potassium bichromate	50	50	50
Prussian blue (dry)	25	50	100
Oxalic acid.....	4	7	15
Potassium ferrocyanide.....	5.5	10	13

The lead acetate and litharge are together converted into basic acetate in the manner described in a former paper (this Journal, 1891, 709). This lead solution is run into a large tub filled with water to about one-third. Oxalic acid and ferrocyanide are then dissolved in about 60 gallons of water, and to the boiling solution is added the finely-powdered Prussian blue. After half an hour's boiling the bichromate is added to the solution, and the lead salt is then precipitated with these united solutions. The precipitated green is washed in the usual manner; it is the finest and fastest chrome green which is known at present.

If desired, neutral lead acetate or lead nitrate may be used instead of the basic acetate, but it is worth mentioning that different lead salts produce also greens more or less differing in appearance. This is rather difficult to explain, but it is nevertheless a well-known fact, and very probable in some relation to the often-made observation that yellows made from nitrate of lead give very bad results in calico printing, only yellows from lead acetate being available for this purpose.

Like the chrome yellows, the chrome greens are generally "filled" with some indifferent mineral "base," not only in order to produce lower grades, but also to give them such physical properties as are required to make them suitable for various applications, properties which the pure greens either do not possess at all or in an insufficient degree. It is not only of importance which "bases" have been added to a green, much depending also on the manner in which the two have been combined. The most important of these bases are barium sulphate, mineral white (gypsum), china clay, alumina hydrate.

Barium sulphate and mineral white are principally used for the manufacture of low grades of green, and it is advisable to use for moderate "reductions" exclusively mineral white; for high "reductions," mineral white and barium sulphate are preferable, generally the barium sulphate constituting the larger portion of the mixture of the two "bases." For purposes where such substantial bases as the two before mentioned are not desired, as in the case of paper-staining, alumina hydrate and china clay are used. The alumina hydrate is now always prepared from aluminium sulphate by precipitation with sodium carbonate, but great care must be taken to have the alumina salt free from iron, 0.008 per cent. of which will give the otherwise brilliant white aluminium hydrate a peculiar dead and dirty-looking shade, the effect of which on the shade of a chrome green is greater than might be anticipated. With regard to the china clay employed as a "base," that which in composition comes nearest to the formula, $(Al_2O_3)_2(SiO_2)_3, 3H_2O$, will be found the best.

It used to be customary at one time to add the whole of the "base," which was intended to be incorporated in a chrome yellow or chrome green, to the solution of the lead salt before precipitation, the idea evidently being to precipitate the chrome pigment upon the base, and so to obtain as close a union as possible between pigment and base. This method is now practically abandoned as it has been found more advantageous to either add the base to the solution of the lead salt at the same rate as the precipitation of the pigment is proceeding, *i.e.*, simultaneous with the latter, or to add the base to the pigment after precipitation. In

each of the two cases the "base" or mixture of "bases" is suspended in a sufficient quantity of water and run, either during or after the precipitation of the pigment, into the precipitation tub through a moderately fine sieve (No. 40). These remarks refer particularly to the use of barium sulphate and mineral white.

If aluminium hydrate is employed as "base," a special method has to be followed in order to ensure a perfect union between aluminium hydrate and the chrome pigment, the specific gravities of which are so very different. To the precipitated pigment is added a solution of sulphate of alumina, about 15 per cent. of the whole quantity which it is intended to precipitate, and subsequently an equivalent quantity of soda carbonate is slowly and carefully run into this mixture in order to precipitate aluminium hydrate. In this way a most intimate mixture of the chrome pigment and a small quantity of aluminium hydrate is obtained. The evolution of carbonic acid which accompanies the precipitation of the aluminium hydrate, assists very materially in producing the compound pigment in a very voluminous form, in which it can readily be mixed with almost any desired quantity of ready-formed aluminium hydrate. Where chrome pigments are intended to be filled not only with aluminium hydrate but also with sulphate of barium, mineral white, or china clay, it is advisable to add these, during or after the precipitation, before the incorporation of any of the aluminium hydrate, which is then proceeded with as above described.

A matter of very great importance in the manufacture of chrome greens is the quality of the Prussian blue employed for this process, an unsuitable blue producing very poor results even with the best yellows. Practically pure Paris blue is manufactured in a great variety of shades, ranging from a bright ultramarine to a very deep blue-violet. The lighter shades of Prussian blue are especially useful for the manufacture of zinc greens, the dark shades are the most suitable for chrome greens. In this manner particularly three shades of pure Paris blue are used, *viz.*, Paris blue ultramarine shade (milori blue, steel blue, Chinese blue), Paris blue indigo shade, and Paris blue-violet or "red" shade.

The principle of the manufacture of these three blues is the same in every case, namely, the oxidation of the "white paste" obtained on the precipitation of potassium or sodium ferrocyanide with a ferrous salt. The shade of the blue is greatly influenced by the conditions under which it is produced, the most important of which are (1) the proportions of ferrocyanide and ferrous salt used in the precipitation of the white paste, (2) the particular ferrous salt employed, (3) the oxidising agent and the acid in the presence of which the oxidation is performed.

1. *Prussian blue ultramarine shade:* 100 lb. of ferrocyanide are dissolved in 450 galls. of water, the solution is heated to boiling, 25 lb. of hydrochloric acid 28° Tw. = 1.14, are added, and the boiling continued for half an hour. Into this boiling solution is then run a solution 65 lb. of ferrous chloride ($FeCl_2$) in 50 galls. of boiling water; or the two solutions are run simultaneously into a large tub partly filled with boiling water. After precipitation, the contents of the tub must be well agitated and the boiling continued for at least half an hour. The tub is then filled up with cold water and the precipitate left to settle for three days, when the supernatant liquor is siphoned off, the precipitate boiled up with steam and subsequently oxidised by adding to the boiling mass in turns 25 lb. of hydrochloric acid and 12 lb. of chlorate of potash or soda. The oxidation being complete, the tub is again filled up with cold water and the acid completely washed out of it by decantation. The water used for the washing is of great importance, and ought to contain no lime, especially not in the form of carbonate, very small quantities of which suffice to destroy the "bloom" of these pigments. If, however, a hard water must be used, acidifying with acetic acid will almost entirely prevent its harmful influence.

11. *Prussian blue indigo shade:* 100 lb. of ferrocyanide and 90 lb. of ferrous sulphate are dissolved in separate tubs, and to the solution of the ferrous salt 25 lb. of sulphuric acid 168° Tw. = 1.84, and $1\frac{1}{2}$ lb. of stannous chloride are added. The two solutions are run simultaneously into the

precipitating tank, which is partly filled with boiling water; the boiling is to be continued during and for about 30 minutes after the precipitation. The white paste is again left to settle for some days and then oxidised either by means of nitric acid or by means of bichromate.

In oxidising with nitric acid the white paste is run into a rectangular lead-lined vat, with a barrel-shaped bottom and a hood on the top which has an opening on one of the narrow sides only, allowing an agitator to be inserted in order to mix the paste during the process of the oxidation. Opposite to that opening a spacious clay pipe is fitted in the hood, through which the noxious vapours developed during the oxidation may be drawn in a chimney or furnace. A lead pipe carrying a funnel penetrating the side of the vat and terminating on the bottom of it is arranged. Through it 50 lb. of sulphuric acid 168° Tw., and subsequently 32 lb. of nitric acid 78° Tw. are added to the white paste, which is well mixed all the time. After the development of nitrous acid from the mixture has ceased, the blue is transferred to the washing tubs to be freed from acid. If bichromate is used for the oxidation of the white paste, the oxidation may be performed in the precipitation tub after having run off the supernatant wash-water. 50 lb. of sulphuric acid are added to the white paste, and the oxidation is effected at the boiling temperature, by adding gradually a solution of 28.5 lb. of bichromate in 28 galls. of boiling water. The chromium sulphate clings to the blue very obstinately, and great care must be employed to wash it out completely.

III. Prussian blue red shade: The precipitation of the white paste for this blue is performed in exactly the same manner as above described, using 100 lb. of ferrocyanide and 90 lb. of ferrous sulphate. The oxidising agent used is ferric sulphate, which produces blues of an excellent dark shade very suitable for the ordinary chrome greens. Before oxidising the supernatant water is run off the white paste, to which 25 lb. of sulphuric acid 168° Tw. are added and the mixture heated to boil. 150 lb. of ferric sulphate (ferric liquor) prepared as below are then added, the boiling being continued for half an hour. The filtrate from a sample of the oxidised blue must distinctly show the presence of an excess of ferric salt. The oxidised blue is purified by washing in the usual way.

Although the ferric liquor is a commercial product, it is advisable to prepare it especially for this process, the commercial article containing frequently a large proportion of ferrous salt. It is best prepared in a number of large Woulf's bottles (tourils) which are connected amongst themselves, with the usual clay pipes and with a chimney or absorption tower to draw away the large quantities of nitrous acid evolved. The bottles are charged with 10 galls. of water, 64 lb. of nitric acid 78° Tw., and 60 lb. of sulphuric acid 168° Tw. To this hot mixture 300 lb. of finely-crystallised or ground ferrous sulphate are slowly added. The oxidation proceeds very rapidly but quietly. It is advisable to keep the bottles warm during the operation, for which purpose they are placed in a steam-heated wooden box from which only the tops of the bottles and the bottom taps for drawing off the liquor project.—C. O. W.

PATENTS.

Improvements in and relating to the Manufacture of Paints or Paint-Stocks. G. W. Scollay, New York, U.S.A. Eng. Pat. 2382, February 10, 1891.

THE inventor combines the preparation of paint or paint-stock with the refining of vegetable oils in the following ways:—

1. By mixing with commercial yellow cotton-seed oil a suitable quantity of ochre or other pigment, which combining with the impurities of the oil forms a paint or paint-stock, at the same time refining the oil. When ochre is used all uncombined water must first be expelled. Umbers must be heated until they assume a deep brown colour; siennas until they show a light red colour. Overheating, causing all constitutional water to be expelled ought to be guarded against, as it renders the pigments inert. From four to twelve parts of the grease are mixed with one part of above pigments, and after about 40 minutes the oil is separated from the insoluble sediment by any convenient means. In this way a superior quality of oil and a merchantable paint or paint-stock are obtained.

2. A barrel of oil is mixed with from two and one-half to four pounds of caustic soda, agitated for about 40 minutes, then left to settle. The refined oil is drawn off, the residue is soap or soap-stock, which may be converted into paint or paint-stock by means of chloride of calcium and similar salts.

3. The oil is first partially refined by treating it with a small quantity of caustic alkali, and the refining is subsequently completed by treating with ochre.

4. The oil may be treated with any metallic salt and caustic alkali simultaneously, or by any combination of the above described reagents.

Paints or paint-stocks of the above description are converted into paints of greater variety and brilliancy in colour in the following manner:—

To make yellow paint, soap stock is converted into lead plaster by means of acetate of lead, this lead-soap is then acted upon with bichromate or chromate of soda.

Blue paint is obtained by treating the soap-stock with iron salts first and then with ferrocyanides.

Green paint is produced by boiling the soap-stock with arsenious acid, on addition of copper sulphate a vivid green is obtained.

The paints may be washed with water and dried at a moderate heat.

The paint or paint-stock obtained as above described is used for treating or filling pigments in order to make them less absorbing. The pigments are mixed with those paints or paint-stocks and 10 per cent. of naphtha. On heating the paint or paint-stock is dissolved and penetrates into the pigment, the naphtha is volatilised. Pigments treated in this manner can be converted into paints with much less oil than the untreated pigments, and the paints so obtained are of excellent drying power.—C. O. W.

A New or Improved Composition of Ink for Reproduction of Copies by the Manifold Process and the like. W. Sherwood, Loughborough. Eng. Pat. 5437, March 26, 1891.

See under VI., page 346.

Improvements in the Production of White Lead or Basic Carbonate of Lead from Galena or Sulphide of Lead Ore, or from suitable Residual Products or Substances containing Sulphide of Lead. Watson Smith and W. Elmore, London. Eng. Pat. 5501, March 28, 1891.

THIS is essentially a combination of known methods for the production of oxide of lead from galena, sulphide of lead ore, or from other substances containing sulphide of lead, with MacIvor's method (Eng. Pat. 10,426, 1888) and MacIvor and Smith's process (Eng. Pat. 16,093, 1890) for the production of white lead by the action of acetate of ammonia and carbonic acid, with various modifications, upon oxide of lead.

Solutions of acetate of lead or tribasic acetate of lead prepared in the manner described in the above-mentioned patents contain copper if the galenas or other sulphides of lead used for the preparation of the oxide of lead were contaminated in this manner. From the above solutions the copper is removed, after all, or practically all, lead has been precipitated, by slightly acidulating the solutions with acetic acid, and either treating it with zinc, preferably in the form of "gossamer zinc," or with an electric current, employing carbon electrodes, the copper being deposited upon the cathode.

The inventors describe in detail the process of carbonating the ammoniacal solutions of lead acetate by a fractionating method in order to obtain white lead of uniform and high basicity and at the same time free from copper, which latter may cause yellow discolouration of the pigment.

The galena or other sulphide of lead may be at once smelted for reduction to metal, the eliminated sulphur being converted into sulphuric acid, or sulphites, or bisulphites respectively. The rough metallic lead is melted on a bone-ash or clay bed and exposed to a current or blast of air to form litharge, which is removed by means of suitably-arranged overflows or mechanical means. The first portions of litharge formed are contaminated with iron, and are smelted with a fresh lot of ore or sulphide. Those fractions containing only most minute traces of iron are used for solution in acetate of ammonia.

Any silver contained in the original ore or sulphide of lead is left on the bone-ash or other bed, and may be recovered by smelting with a suitable flux.—C. O. W.

Improvements in Pigments having a Lead Basis. C. A. Bingham, Manchester. Eng. Pat. 5681, April 2, 1891.

This is a process devised to utilise the plumbic hydrate obtained in accordance with the inventor's process of manufacturing nitrate of ammonia (Eng. Pat. 5442, 1890). The pigments are prepared by adding to the plumbic hydrate solutions of suitable aniline colours. In some cases the operation is aided by heating the mixtures.

—C. O. W.

Improvements in or appertaining to Preservative Coatings for Iron or other Structures. J. Robson, Southsea. Eng. Pat. 5977, April 7, 1891.

The invention refers to a mixture of rosin pitch, residues from the distillation of mineral oil or ozokerite, American asphaltum, melted with sufficient paraffin wax to give fluidity and freedom from stickiness when hot.—C. O. W.

Improvements in the Treatment of Gums and the Preparation of Varnishes therefrom. G. H. Smith, London. Eng. Pat. 7036, April 23, 1891.

The patentee claims the utilisation of the property observed by him, to be possessed by soft readily soluble gums, of aiding the solution of harder and more refractory gums, in an appropriate solvent, such as linseed or other oil. He gives as an example the treatment of kauri gum for making a varnish therefrom. About one pound of a soft gum, such as gum dammar, is dissolved in linseed oil and added to 16 lb. of kauri gum, and heated to a temperature of from 400°–500° F. whereby solution is said to be effected. In place of gum dammar "a small quantity of the liquid products of distillation of these gums and resins, such as is given off upon the treatment by fusion of gums in ordinary processes of varnish making as now practised, and which liquid products of distillation are now practically wasted" may be used.—B. B.

Improved Manufacture of Size Paint. A. J. Boulton, London. Eng. Pat. 7695, May 4, 1891.

ONE lb. wheat flour is boiled to form a paste, and a solution of 1 oz. of alum is added.—C. O. W.

Improvements in the Process of and Apparatus for the Manufacture of White Lead. A. Honman and V. Vullier, Williamstown, Victoria. Eng. Pat. 8022, May 9, 1891.

The invention consists mainly in preserving the basic acetate of lead at a uniform temperature of about 120° F., and in the conversion into white lead of the sulphate of lead, produced in the roasting of sulphide of lead ore and dissolved in caustic soda, caustic potash or ammonium acetate, by precipitation with a solution of carbonate or bicarbonate of soda, potash or ammonium. In carrying out the process ordinary galena is roasted in a reverberatory furnace of special construction at a low red heat for a sufficient time to drive off the greater part of its sulphur. When this is accomplished the roasted ore is placed in one of a series of tinned copper cylinders where it is treated with a hot solution of lead acetate at 15° B. and steam. The solution so obtained is run into settling tanks, and from these the clear solutions are conveyed into vats in which the liquor is kept at an even temperature of 120° F., when it is subsequently treated with a current of carbonic acid, the supply of which is cut off as soon as the specific gravity of the solution has decreased to 15° B. The precipitated white lead is drawn off then from the bottom of the tanks which are at once refilled with a fresh quantity of basic acetate of lead until the original density of 18° B. is again reached, when the carbonating operation is at once repeated. The lead liquor drawn off with the carbonate of lead is separated from the latter and pumped back to the above-mentioned extraction cylinders, and when the oxide of lead therein has been entirely dissolved the sulphate of lead which forms portion of the residue is dissolved by a solution of caustic soda or potash. The solution thus made is conveyed to a tinned copper pan wherein the white lead is precipitated by means of a solution of carbonate of soda or potash or ammonia.

The construction of the special plant devised for the carrying out of these processes by the inventors cannot be understood without the drawings accompanying the specification.—C. O. W.

Improved Rust- and Acid-Proof Paint. R. Lender, Berlin. Eng. Pat. 20,274, November 21, 1891.

This invention relates to a rust- and acid-proof paint for metals and other materials. Natural iron silicate is the chief ingredient, which is reduced to a fine powder and ground into a paint with a suitable quantity of ozonised or otherwise oxidised linseed oil or varnish.—C. O. W.

Improvements in the Manufacture of Venetian-red. W. J. Wigg, Frodsham, Cheshire. Eng. Pat. 21,279, December 5, 1891.

This invention consists in an improved method of uniting and combining Venetian-red with indifferent white bodies, such as powdered barytes, gypsum, or the like. Residual copper liquors containing about 10 per cent. of chloride of iron and 16 per cent. of sulphate of soda is treated with a large excess of milk of lime or other similar oxide, and after precipitation the mass is oxidised with a current of steam and air. Afterwards the precipitate is washed and filter-pressed. The specification is accompanied by a set of drawings.—C. O. W.

Improvements in Inks for Printing, Stamping, and the like. C. M. Higgins, New York, U.S.A. Eng. Pat. 93, January 2, 1892.

The patentee states that castor oil, oil of cassia and carbolic acid, "and its substitute creosote," have no action on india-rubber, and are well suited for forming a non-drying ink for stamps, type writer ribbons, and the like. Aniline dyes are readily soluble in the mixture. As an example of a stamp ink there is quoted the following recipe: four fluid ounces of castor oil are mixed with one fluid ounce each of carbolic acid and oil of cassia, and one ounce of ethyl violet or other aniline dye dissolved therein. The solution takes place cold, but may be aided by stirring and heating. The proportions may be varied according to the purpose in view.

XVI.—SUGAR, STARCH, GUM, Etc.

A Crystalline Magma of Invert-Sugar. F. G. Wiechmann. School of Mines Quarterly, 1892, 13, 149—151.

A SAMPLE of granulated sugar polarising 99.9—100 was inverted with hydrochloric acid (sp. gr. 1.2) using 0.0265 per cent. on the weight of sugar; the product was a colourless syrup, having a density of about 80° Brix, (43.11° Beaumé) and contained 84.8 per cent. of invert-sugar; it had a slightly acid reaction. The syrup was placed in a well-corked flask, and was exposed to diffused and direct sunlight at a temperature of 24° C., and after three months, it had become a white crystalline magma.

An aqueous solution of the magma having a sp. gr. 1.1427 at 15° (= 32.7° Brix) was prepared; $\frac{100}{32.7} = 3.058$; hence 3.058 grms. of the solution contained 1 gm. of dry substance.

(I.) 39.827 grms. of this solution (= 13.024 grms. on the dry substance) were made up to 100 cc.; of which 50 cc. were further diluted to 1 litre, and 35 cc. of the latter solution (= 0.2279 grms. of dry substance) were added to 50 cc. of boiling Fehling's solution (Saxhlet's formula) together with 15 cc. of water, the boiling being maintained for two minutes. As the mean of three experiments 0.394 gm. of metallic copper was obtained; according to Meissl (Zeits. d. Ver. f. Rübenz. Ind. 1879, 1034), 0.2278 gm. of pure invert-sugar reduces 0.404 gm. Cu, so that the amount of copper obtained corresponds to 0.2212 gm. of invert-sugar, and the sample contained 97.06 per cent. of invert-sugar and 2.8 per cent. of sucrose on the dry substance.

(II.) 30.58 grms. of the above-mentioned solution (32.7° Brix), corresponding to 10 grms. of dry substance were dissolved in water, diluted to 100 cc. at 17.5° C. and polarised at 20; this solution gave $[\alpha]_{D, 20} = -18.16$,

whereas Gabbe's value for a 10 per cent. solution of pure invert-sugar is $[\alpha]_{D, 20} = -20.018$; assuming that the 2.8 per cent. of sucrose preserves its usual optical properties, the value corrected for the latter is $[\alpha]_{D, 20} = -20.02$.

26.048 grms. of the magma were dissolved in water, made up to 100 cc., and the solution polarised at 20° in a 200 mm. tube. The reading immediately after preparation was 7.9, and this gradually increased to -23.3 at the end of 23 hours. 50 cc. of the solution were heated with 5 cc. of hydrochloric acid (sp. gr. 1.2) at 67° C. for five minutes, when it was cooled, made up to 100 cc. and polarised, the readings being -26.2 to -26.6, which remained constant after 20 hours.

A solution of the magma corresponding to 10 grms. of the dry substance in 100 cc. had a sp. gr. 1.03853 at 17.5° C., whilst the specific gravity of a solution of pure invert-sugar of this concentration is, according to Herzfeld, 1.03901.

Five grms. of the magma were placed in a test tube together with a thermometer, and slowly heated in a water-bath. It commenced to liquefy at 50°, and liquefaction was complete in 29 minutes, the temperature then being 60.5° C. After 12 days it commenced to resolidify, and crystallisation progressed slowly.

Two grms. of the magma placed in a vacuum over concentrated sulphuric acid lost 9.7 per cent. in 645 hours. The author considers it probable that the transformation of the 2.8 per cent. of sucrose is only a question of time; the specimen is being exposed to full daylight, and should complete inversion be effected, a careful determination of the relative amounts of dextrose and levulose present will be made, and the question as to whether it consists of pure invert-sugar in the crystalline form elucidated. (Compare Wohl and Kollrepp, this Journal, 1890, 957.)

—A. R. L.

Pine-Tree Sugar. H. W. Wiley. J. Amer. Chem. Soc. 1891, 13, 228—237.

BERTHELOT examined a sugar from *Pinus lambertiana* (Ann. de Chim. 1856 [3], 46, 76), and found it to have the empirical formula $C_6H_{12}O_5$, a specific rotatory power $[\alpha]$, 58.6, and to form a compound, $C_6H_{12}O_5 \cdot 2 PbO$, when treated with ammoniacal lead acetate; also that the rotatory power was unaltered when the sugar was treated with concentrated hydrochloric acid at 100° for 10 minutes. The author commenced the study of pine-tree sugar from *Pinus lambertiana* (California), but a paper by Maquenne on the same subject (this Journal, 1890, 311) anticipated his work to a large degree. Maquenne's sugar, which he named β -pinite, was obtained from *Pinus lambertiana* (Nebraska), but as this tree does not grow in Nebraska, Maquenne must have been mistaken as to the origin of the sugar. The author concludes from a comparison of Berthelot's and Maquenne's work that the compounds obtained by both these chemists are one and the same, and that Berthelot's specific rotatory power is too low. In the present research the following method of isolating the sugar is adopted. The crude sugar is boiled with successive portions of 95 per cent. alcohol to remove some of the colouring matter, the dried residue dissolved in water, and the solution filtered while hot through animal charcoal; the filtrate is treated with basic lead acetate, and the lead precipitated from this filtrate by sulphuretted hydrogen, the filtered solution being concentrated and once more filtered through animal charcoal. The clear solution is evaporated to the crystallising point, agitated, and allowed to remain, when crystals separate in 2—4 days; the concentrated syrup may also be placed in a jar surrounded by ice and three times its volume of absolute alcohol stirred in, when the whole of the sugar separates in 10—15 hours; in either case the crystals are washed successively with alcohol and ether, dried at 50°, and finally placed over concentrated sulphuric acid until of constant weight. The specific rotation appears to be independent of the concentration, and was found to be $[\alpha]_D = 65.01$, thus confirming Maquenne's value (*loc. cit.*). When the sugar is distilled with sulphuric acid a trace of furfural is produced;

whilst on oxidation with nitric acid large quantities of rhodozone acid are obtained, and a small quantity of a yellowish substance, which is, perhaps, pieric or croconic acid. It does not yield an osone with phenylhydrazine, but when treated with calcium, barium, or strontium hydroxides, precipitates are produced which become crystalline on remaining.

In conclusion, the author refers to the formation of β -inosite (Maquenne, *loc. cit.*), and also to Combes' work (this Journal, 1890, 311), according to whom Maquenne's β -pinite is identical with matezite, and β -inosite with matezodambose.—A. R. L.

The Specific Rotatory and Cupric Reducing Power of Invert Sugar and of Dextrose obtained from Cane Sugar by means of Invertase. J. O'Sullivan. *Proc. Chem. Soc.* 1892 [1893], 56.

See under XXIII., page 372.

XVII.—BREWING, WINES, SPIRITS, Etc.

Cask Plant. A. Hartley. *Trans. Inst. Brewing*, 1892, 5, 85—111.

The first portion of the paper treats of coopers' work, and includes a detailed account of the different varieties of oak used in making brewers' casks, the sorting of the staves, and the different ways of sawing them, the judging of the workmanship of a cask, branding, numbering, &c. In dealing with cask capacity, it is pointed out that the amount of wood surface exposed to the beer is very much larger in small casks than in large ones.

A few words on repairing are followed by a list of coopers' prices current in London and Burton.

The seasoning of casks is usually accomplished by soaking them for 1—2 days in a solution containing about 1 lb. salt and $\frac{1}{2}$ lb. soda to the barrel. After emptying the casks are filled with cold water for an hour or so and then scalded out and steamed.

The same treatment may be used with advantage for curing acid casks, the solution being made double the strength, and followed by treatment with sulphurous acid.

With reference to the cure of mouldy or stinking casks, a great deal depends on the extent of the evil: if only slight the casks should be scrubbed and treated with sulphurous acid, if more pronounced, they should be filled with warm water containing about 1 lb. to the barrel of chloride of lime and a pint of strong sulphurous acid; if the casks are very bad, the staves must be shaved or the casks broken up. Occasionally lengthened exposure of the unheaded casks to the weather will cure stinkers. Another method of curing them is by the use of enamel, but this is not recommended.

The best way of storing empty casks is to stack them with their heads out and the bunghole downwards; or the casks as they are received back containing the hops and bottoms may be placed in the store until required; this is, however, rather risky in warm weather, or the casks may be cleaned as soon as received, and then stopped down with a little sulphurous acid.

With regard to the general preparation of casks for filling, the author does not consider unheading necessary, but if in good condition recommends rinsing with hot water followed by treatment with sulphurous acid and testing with steam.

Great stress is laid on the "passing-in" of casks; none should be passed which have the slightest taint about them.

—A. L. S.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A.)—CHEMISTRY OF FOODS.

The Glycerin and Artificial Butter Industry under United States Patents. E. Starek. *School of Mines Quarterly*, 1892, 13, 131—141.

See under XII., page 353.

Zinc in Preserved Foods. J. E. Allen. *Chem. Zeit.* 1891, 15, 1714.

It is well-known that copper often occurs in preserved foods, and is in fact wilfully added to improve the colour of the articles, but addition of zinc seems to serve no useful purpose.

The author has, nevertheless, tested samples of preserved peas, which, although free from copper, contained a large proportion of zinc. They had a pleasant green colour.

—L. de K.

On the Occurrence of Tin in Canned Food. H. A. Weber. *Journ. Amer. Chem. Soc.* 1891, 13, 200—207.

The following method was employed:—The contents of each can were emptied into a large porcelain dish, and the condition of the inner portion of the can noted; after thoroughly mixing the contents, 50 grms. were weighed off and incinerated in a porcelain dish. The residue was treated with an excess of concentrated hydrochloric acid evaporated to dryness, and the residue extracted with dilute hydrochloric acid, filtered and washed, the insoluble residue being again incinerated and treated as above. The solution thus obtained was treated with hydrogen sulphide, the precipitate collected after 12 hours, and the tin weighed as stannic oxide. The following table shows the amounts of stannic oxide obtained in the various samples tested:—

Sample.	SnO ₂ Grains per lb.	Remarks.
Canned pumpkin	2.97	
" "	3.11	Can corroded.
" "	0.38	"
Hubbard squash	1.85	Can badly corroded.
Canned tomatoes	0.81	Inner coating corroded.
" "	0.98	Can corroded.
Canned peas	0.48	No visible corrosion.

Sample No. 7, "Canned Peas," contained an amount of copper equivalent to 3.95 grains per pound of copper sulphate, and this was in addition to the above-mentioned tin. It will thus be seen that all the samples examined, except the condensed milk, contained an amount of tin salts likely to be injurious to health.—A. R. L.

(B.)—SANITARY CHEMISTRY.

Further Observations on the Efficacy of Sand-Filters as employed in the Waterworks at Zürich. J. f. Gasbelenchtung, 1891. 34, 704—709.

Numerous bacteriological examinations, during a number of years, of the Zürich water supply, before and after filtration through sand, have led to certain conclusions which may be summarised as follows:—

Fränkel and Piefke's assertion that sand-filters offer no absolute protection against pathogenic organisms is disputed, as being not applicable to all sand-filters; and their statement that the number of bacteria present in the filtered water is simply proportionate to the rate of filtration and to the number of organisms existing in the water originally, is shown to be erroneous. On the contrary, the author finds that under the conditions obtaining at Zürich, the number of developable spores in the filtered water is small and fairly constant, and quite independent of the degree of original pollution or the rapidity of filtration (3 to 12 metres per day). It is of importance, however, that the filters be allowed time to acquire their "normal" working condition, and that the rate of filtration be uniform. In the case of new filters, or after cleaning, &c., the action is for some time abnormal, and the water during filtration may even take up organisms from the sand. This fact may possibly explain the bad results obtained during the trial of sand-filters at the Stralau waterworks in Berlin (this Journal, 1890, 642—643).

It may be mentioned that the bulk of the Zürich water-supply is drawn from the lake, and after filtration it is very constant in composition, both chemically and bacteriologically (see also this Journal, 1889, 998).—H. T. P.

PATENTS.

Improvements in the Means employed for the Purification and Decolorisation of Water, Dye, and other Manufacturing Refuse-liquors, Sewage, or other Aqueous or Saline Liquids. W. H. Watson, Bolton. Eng. Pat. 4177, March 9, 1891.

The inventor employs for the above purpose a filter-bed composed of some kind of iron slag, such as "tap cinders," "mill-cinders," "mill-slag," blast-furnace slag, basic or phosphatic slag, &c., either alone or in conjunction with sand (preferably refuse moulding sand), gravel, cobbles, charcoal, &c.—H. T. P.

Improved Means for Delivering and Distributing Polluted Water upon and over a Filter-Bed. J. D. Garrett, Southwold. Eng. Pat. 4677, March 16, 1891.

The apparatus employed consists of an over-shot water-wheel mounted in bearings on a travelling carriage which is arranged to pass automatically on rails over a long filter-bed. A comparatively short trough is attached to the frame of the carriage and moves with it. The forward end of this trough overhangs the water-wheel, whilst the other end is supported on rollers which run on rails extending the whole length of the filter-bed. Over and parallel to the moving trough is a fixed trough equal in length to the filter-bed, and provided at suitable intervals with valves for the exit of the water that is discharged into it from a drain pipe. These valves are raised and lowered one after another as the carriage travels along by means of a projecting rib attached to the moving trough. The sewage which flows from the fixed into the moving trough passes to the water-wheel, causing it to revolve, and subsequently falls on the filter-bed. The carriage, and the hopper for distributing

earth, &c., over the filter-bed, are driven by means of belts or chain gearing from the shaft of the water-wheel. The apparatus is provided with reversing gear, operated automatically, as may be desired. The filter-bed is preferably constructed of concrete, and is covered with a layer of earth, &c., spread out between walls of rushes and perforated tiles. The polluted water, falling on the filtering medium, soaks through it laterally, and passing through the perforations in the tiles, finds its way into channels on each side of the bed.—H. T. P.

Improved Apparatus applicable to the Cleansing or Filtration of Sewage and other Liquids. W. Birch, Manchester. Eng. Pat. 7466, April 30, 1891.

This apparatus is more particularly intended for removing the suspended matter from sewage, &c. It consists of a series of tanks arranged on the same level, or of a long sluice divided into separate compartments by means of transverse partitions, the upper edges of which are below the level of the edges of the sluice. The first of these partitions is preferably made somewhat higher than the rest. The sewage or other liquid is discharged into the first tank, which it fills. It then overflows into the second, and so on until all the compartments are filled, after which the liquid flows in a level stream over the tops of the partitions. The bulk of the liquid in the tanks being comparatively stagnant, the particles in suspension settle, and, passing through a flat or conical perforated false bottom, fall on the floor of the tank. Each compartment is provided with a flushing pipe below the false bottom, by means of which the deposit of sludge may be periodically removed.—H. T. P.

Improvements relating to the Conversion into Manure of the Refuse and Foul Matters from Cities and Towns. L. Lamattina, Rome, Italy. Eng. Pat. 22,192, December 18, 1891.

According to this process, town refuse is converted into manure by subjecting it to ammoniacal fermentation. By this means putrefactive fermentation and the possible development of pathogenic organisms are arrested, and all danger to public health is avoided. The inventor proceeds as follows:—Upon an impermeable basis of clay or cement, heaps, 3—6 metres high, are constructed of farm dung, town refuse, and earth in alternate layers, each set of layers being slightly moistened with water. At regular intervals iron rods are built into the mass in such a manner that when withdrawn, holes are left for the insertion of a thermometer. The heaps are preferably arranged in pairs, the two beds being placed end to end and sloping in opposite directions. A pit is dug in the ground between the two heaps, and suitable gutters are provided so that the drainings from the manure may run into it. During fermentation the drainings are continually pumped back on to the heaps, and the ammonia and sulphuretted hydrogen formed are absorbed by scattering over every alternate set of layers of the heap a layer of ground ferrous sulphate. When the temperature of fermentation has fallen to 30° C. an extra layer of earth is spread on the heaps and they are left for three months, the edges of the beds being watered once or twice weekly during the first month. After this time the heaps will have diminished in bulk by about one-third, and the manure will be fit for use. The manure thus obtained is said to be greatly superior to ordinary farm dung.—H. T. P.

(C.)—DISINFECTANTS.

The "Bordeaux Mixture," a Remedy for Vine Milder and Potato Disease. M. Perret. "Standard" Agricultural Reports.

An important communication was made by M. Michel Perret at the recent meeting of the National Agricultural Society of France in relation to the preparation of the famous Bordeaux mixture in a form at once innocuous to foliage, more speedily active than the ordinary mixture, and

less liable to be washed away by rain. It has been found that the copper in the mixture is so slowly soluble that the solution does not keep pace with the progress of vine mildew or potato disease in the case of a virulent attack. Moreover, when sulphate of copper is simply mixed with water, the acid salt, in drying, is concentrated, and injures the foliage to which the mixture has been applied. It has been suggested that ammonia should be used to neutralise the sulphate of copper, but the sulphate of ammonia thus produced is nearly as injurious to the foliage as the sulphate of copper is. Therefore it was desirable to find a harmless dissolvent of the copper, and sugar, on account of its affinity for the bases, suggested itself to M. Perret. Accordingly he set himself to obtain the solution of copper by forming saccharate of lime, which he added to the sulphate of copper, thus producing a double decomposition by the reaction of the sulphuric acid on the lime, and by that of the sugar on the copper, forming sulphate of lime and soluble saccharate of copper. Now it is indispensable to maintain an excess of lime in order that the mixture may remain alkaline, and it is difficult to determine the limit of saturation in making the ordinary Bordeaux mixture. But where sugar is added a simple phenomenon gives certitude on this point. The formation of saccharate of copper takes place only in the presence of an excess of lime, and the complete saturation of the copper is verified at the moment when the mixture shows a blue tinge, the unsugared Bordeaux mixture being colourless. Thus M. Perret has been able to determine the correct proportions of the ingredients, and his prescriptions, converted into English quantities, will be valuable to those who intend to make experiments during the present season. Twenty pounds of quicklime are dissolved in 80 gallons of water, and to this solution 20 lb. of molasses dissolved in 10 gallons of water are added, while stirring briskly. Lastly, 20 lb. of sulphate of copper, previously dissolved in 10 gallons of water, are also added. Thus, 100 gallons of a mixture are obtained which deposits slowly, does not enumber the distributing machine, and yet sticks well to the foliage, in spite of a moderate washing by rain. The use of molasses instead of sugar causes the mixture to assume a greenish hue.

PATENTS.

Improvements in the Manufacture or Production of Ortho-xydiphenyl-carbon Acid. B. Willcox, London. From F. von Heyden, Nachfolger, Radebeul, Germany. Eng. Pat. 5122, March 21, 1891.

See under IV., page 344.

Improvements in or Relating to the Manufacture of Disinfectant Tablets or Blocks, or the like for Use in Water-Closets, Urinals, Drains, and other Places or Articles. H. B. Thornton, Liverpool. Eng. Pat. 17,421, October 13, 1891.

The disinfectant blocks are prepared by mixing together permanganate of potash, or other disinfectant, paraffin wax, sulphate of calcium or any other suitable cement, and some absorbent material such as asbestos, cotton yarn, pumice stone, cinders, &c. The mixture is made into a paste with sodium hydrate solution, and subsequently moulded into blocks, tablets, or lozenges, &c. Sodium carbonate and salt may be added to the mass at this stage in order to increase the efficiency of the disinfectant. Afterwards the blocks may be coated with paraffin wax or other material, only a small portion of the surface being left bare to allow the liquid in which the blocks are placed to get at the internal substance. In use the blocks may be placed in the tank or other receptacle itself, when the discharge is regular and frequent, but when the discharge is irregular, as in the case of water-closets, the tablet is preferably so arranged that it comes into contact with the water only at each emptying and filling of the cistern.—H. T. P.

An Improved Sheep Dip. A. Robertson, Oban. Eng. Pat. 20,395, November 24, 1891.

The sheep dip in question forms a paste which is said to be freely soluble in four times its bulk of water. From the solution a "dip" may be prepared combining all the advantages of the simple "arsenical" and "carbolic" dips. The paste is made from the following materials:—

	Parts.
"Arsenious acid	2
Carboresylic oil	6½
Carbolic acid	2
Rosin and grease mixture.....	3½
Soda lye.....	1½"

The rosin and grease mixture, previously heated nearly to the boiling point, is boiled with a portion of the soda lye. The arsenious acid dissolved in the remaining lye is then added and the whole thoroughly boiled. Finally the carboresylic oil and carbolic acid are added and well mixed with the other ingredients by stirring.—H. T. P.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

E crescent Resins. M. Bamberger. Monatsh. 1891, 12, 441—463.

The author has previously examined a number of balsams and resins with a view of determining the number of "methoxyl" groups present (this Journal, 1889, 925, and 1890, 659), and in the present paper deals with the nature of the constituents of the resins of the black fir, *Pinus Laricio*, and of the pine, *Picea vulgaris*. Full details of the physical nature of the two resins are given.

1. *Resin of Pinus Laricio*.—This resin is readily soluble in alcohol and ether, almost insoluble in petroleum ether, melts at about 100° C. and turns red on exposure to air. It gives the reaction for phloroglucinol. When it is dissolved in alcohol and the alcoholic solution treated with steam until the alcohol has been distilled off, a portion of the dissolved resin is precipitated whilst a portion goes into solution which separates out in crystalline crusts on standing. This extract, after careful purification, was found to consist essentially of caffeic acid—

which fact was confirmed by converting the acid into its diacetyl and dihydro-derivatives. Smaller quantities of ferulic acid—

and of vanillin—

were also found in the above aqueous extract. When fused with caustic potash the resin yields catechol and proto-catechuic acid, the latter resulting from the decomposition of the ferulic acid.

2. *Resin of Picea Vulgaris*.—This melts at about 100° C. and when treated with steam in alcoholic solution by the above method, yields a solution from which a crystalline residue results upon evaporation. This residue contains para-cumaric acid—

and vanillin. The presence of ferulic acid could not be ascertained with certainty, and in neither of the resins was abietic acid found. On fusion with caustic potash catechol together with a mixture of protocatechuic acid and para-hydroxybenzoic acid, appear to result.—C. A. K.

The Substances contained in the Petals of Gentiana verna.
G. Goldschmidt and R. Jahoda. Monatsb. 1891, 12,
479—485.

The petals of *Gentiana verna*, when extracted with 80 per cent. alcohol, yield a reddish violet solution, from which a dark red sticky mass results on evaporating off the alcohol. This residue is partially dissolved by water, the colouring matter of the solution being precipitated on the addition of lead acetate; the filtrate from the colouring matter, which itself could not be examined owing to the readiness with which it decomposes, appears to contain a mixture of sugars—probably glucose and levulose. The portion of the extract insoluble in water consists of a mixture of three compounds—one of which preponderates considerably, and which can be separated by fractional crystallisation from alcohol. To this chief constituent the name of *Gentiol* is given. It is a white amorphous powder, melting at 215° — 219° C., and which, according to analysis and a molecular weight determination by the cryoscopic method in phenol solution, has the formula $C_{30}H_{48}O_3$. It forms a tri-acetyl compound, and is therefore to be regarded as a trihydroxy-compound, $C_{30}H_{45}(OH)_3$. On oxidation it yields an acid, melting at 127° C., the composition of which was not ascertained owing to lack of material. When distilled over zinc dust in an atmosphere of hydrogen a greenish oil having a tarry smell is formed, which boiled at 210° C. under a pressure of 22 mm. The second body occurring in the above residue forms white crystalline plates, melting at 215° — 217° C. to which the formula $C_{38}H_{54}O_3$ is assigned from analysis, and a determination of the molecular weight. A third substance consisting of a yellow amorphous powder, melting at 240° C., was also isolated from the mixture, but in too small quantity for further examination.—C. A. K.

Contributions to the Knowledge of the Aconite Alkaloids.
Part II. The Alkaloids of True Aconitum napellus.
W. R. Dunstan and J. C. Umney. Proc. Chem. Soc. 192 [108], 42—44.

The authors have examined the alkaloids of true *Aconitum napellus* plants grown by E. M. Holmes at the instance of the British Pharmaceutical Conference. The alkaloids were extracted from the roots by the following process, which precludes the possibility of the occurrence of hydrolysis, &c.—The solution obtained by percolating with cold rectified fusel oil (boiling point 100° — 132°) was agitated with water acidified with 1 per cent. of sulphuric acid, and the resin having been removed by extracting the acid solution so obtained with chloroform, the liquid was made just alkaline with dilute ammonia and extracted with ether, which dissolved out a considerable quantity of alkaloid, but left in solution a further and smaller quantity, which was subsequently extracted by agitation with chloroform. The alkaloid soluble in ether was obtained as a gum-like mass incapable of crystallisation. By conversion into bromhydride it was separated into a crystallisable and an uncrystallisable salt.

The crystalline product was identified as the salt of aconitine, the crystalline and highly toxic alkaloid already described by one of the authors and Dr. W. H. Ince (C.S. Trans. 1891). The alkaloid separated from the pure bromhydride melted at 188.5° (corr.), and afforded on combustion numbers agreeing with the formula $C_{33}H_{45}NO_{12}$. The specific rotation of the bromhydride in aqueous solution was ascertained to be $[\alpha]_D = -29.65$, a value which agrees with that previously recorded. As some doubt exists as to the solubility of aconitine in water, a determination was carefully made with this pure specimen. The mean of two determinations gave 1 grm. in 4,431 grms. of water as the solubility at 22° ; Jürgens had previously recorded the far greater solubility of 1 in 745 at the same temperature.

The non-crystalline bromhydride furnished a gummy alkaloid soluble in ether and alcohol, but only sparingly soluble in water, the aqueous solution being alkaline to litmus, and very bitter, but not giving rise to the tingling sensation so characteristic of aconitine. Not only the alkaloid, but also the chlorhydride, sulphate, nitrate, and aurichloride prepared from it could not be crystallised.

This alkaloid is not identical either with aconine or with the pieraconitine of Wright and Luff. The authors propose to assign to it the name *napelline*, which was first given to the alkaloid now known as pseudoaconitine, and afterwards by Hübschmann to a substance which the work of Wright and Luff showed to be a mixture chiefly composed of aconine. The napelline obtained in the manner described is probably associated with another amorphous alkaloid.

The alkaloid soluble in chloroform was proved to be aconine, the compound which is obtained together with benzoic acid on hydrolysing aconitine.

The roots of true *Aconitum napellus*, therefore, must be held to contain three alkaloids, one of which is crystalline, viz., aconitine, two being amorphous, viz., napelline and aconine. Indications have been obtained of the presence of a fourth alkaloid, which is amorphous and closely resembles napelline.

The authors find that the juice expressed from the roots contains a large proportion of amorphous bases, but very little aconitine, the greater part of this latter remaining in the root, from which it may be extracted, together with the remainder of the amorphous alkaloids, by exhausting with amyl alcohol. The total quantity of amorphous alkaloid obtained amounted to more than twice that of aconitine.

The physiological results so far obtained point to the conclusion that crystalline aconitine is by far the most toxic of the alkaloids contained in *Aconitum napellus*.

Contributions to our Knowledge of the Aconite Alkaloids.

Part III. The Formation and Properties of Aconine and its Conversion into Aconitine. W. R. Dunstan and F. W. Passmore. Proc. Chem. Soc. 1892 [108], 44—46.

Owing to the uncertainty which exists with reference to the product of the hydrolysis of aconitine, the authors have re-investigated the subject, using a pure alkaloid. Wright and Luff have stated that when aconitine is hydrolysed the sole products are aconine and benzoic acid. More recently, however, Dragendorff and Jürgens have asserted that the hydrolysis occurs in two stages, their contention being that benzoic acid and an alkaloid identical with the pieraconitine isolated by Wright and Luff from the roots of supposed *Aconitum napellus* are formed in the first stage, while in the second stage the pieraconitine is hydrolysed into benzoic acid, methyl alcohol, and aconine, which last is the final product of hydrolysis.

The authors have carefully hydrolysed pure aconitine by heating it with water in closed tubes at 150° , and the alkaloid extracted from the solution by ether was proved to be a mixture of aconine with unaltered aconitine. Using pure aconitine, action occurs precisely in accordance with the equation $C_{33}H_{45}NO_{12} + H_2O = C_{26}H_{41}NO_{11} + C_7H_5O_2$, leaving little doubt that aconitine is benzoylaconine.

Anhydroaconitine was obtained by the interaction of aconine and ethyl benzoate at 130° ; as the anhydro-compound is convertible into aconitine, the partial synthesis of the alkaloid thus effected leaves no doubt that it is benzoylaconine.

Up to the present time neither aconine nor its salts have been obtained in a crystalline state. The authors have hitherto been unsuccessful in all their attempts to crystallise aconine, but they have succeeded in crystallising several of its salts, viz., the chlorhydride, bromhydride, sulphate, and nitrate. All these salts are very soluble in water, the chlorhydride being least soluble and the easiest to crystallise; it is best prepared by crystallisation from a mixture of alcohol and ether; when dried at 100° it melts at 175.5° (corr.). The crystals deposited from alcohol have the composition $C_{26}H_{41}NO_{11} \cdot HCl \cdot 2 H_2O$. When dried at 100° they still retain one molecular proportion of water, which is, however, lost at 120° . The aqueous solution is levorotatory: $[\alpha]_D = -7.71^{\circ}$. It combines with auric chloride forming an aurichloride considerably more soluble than the corresponding aconitine salt.

Aconine was prepared from the pure chlorhydride by adding silver sulphate and subsequent treatment of the aconine sulphate with exactly sufficient baryta water. The solution on evaporation furnished a hygroscopic, brittle gum

which refused to crystallise; this melted at 132° (corr.), and on analysis it afforded numbers agreeing with the formula $C_{26}H_{41}NO_{11}$, which is that proposed by Dunstan and Ince from the results of their study of pure aconitine. Aconine is very soluble in water; the aqueous solution is alkaline. Its aqueous solution is slightly bitter and gives rise to a burning sensation in the mouth, but does not produce the tingling which is characteristic of aconitine. In respect of its action on polarised light aconine exhibits the same peculiarity as aconitine. Its salts are levorotatory, whilst a solution of the alkaloid is dextrorotatory, $[\alpha]_D + 23^{\circ}$. When heated with alkalis aconine slowly resinifies.

The examination of various agents on aconine has so far not led to any important results. Nitrous acid fails to attack it. The principal product of its oxidation by alkaline permanganate is oxalic oxide.

By the action of methyl iodide on aconitine a crystalline *aconitine methiodide* ($C_{26}H_{45}NO_{12} \cdot CH_3I$) was obtained, which melts at 219° (corr.). The *aconitine methyldroxide* prepared from the compound ($C_{26}H_{45}NO_{12} \cdot CH_3OH$) is amorphous, and the salts which it yields do not appear to crystallise.

A Study of the Conditions which determine Combination between the Cyanides of Zinc and Mercury; and of the Composition and Properties of the Resulting Double Salt. W. R. Dunstan. Proc. Chem. Soc. 1892 [109], 51—53.

WHEN a solution of zinc sulphate is added to a solution of mercuric potassium cyanide [$HgK_2(CN)_4$], or when mercuric chloride is added to a solution of zinc potassium cyanide [$ZnK_2(CN)_4$], a white precipitate is formed which has been stated, on the authority of Gmelin, to consist of a double cyanide of zinc and mercury of the formula $ZnHg(CN)_4$. This, the author has shown, is not the case (Pharm. J. 3, 20, 653; J. Chem. Soc. Abstr. 1890, 855). The precipitate loses a large quantity of mercuric cyanide when it is washed with cold water, some, however, remaining attached to the cyanide of zinc. Previous experiments seemed to point to the conclusion that the mercuric cyanide thus retained is not combined, but in some manner mechanically entangled by the zinc cyanide. This view is, however, disposed of by further experiments, of which an account is now given.

The precipitate is in many respects a remarkable substance. The amount of mercuric cyanide "retained" is dependent on the amount of water present during precipitation, as well as on the proportion in which the salts interact; the maximum quantity retained is 38.5 per cent. Zinc cyanide having this percentage of mercuric cyanide attached to it in such a form that it cannot be removed by ordinary washing with cold water is precipitated when cold saturated solutions of the two salts are mixed in equimolecular proportions. The washed precipitate is amorphous. Prolonged contact with cold water leads to the gradual removal of mercuric cyanide. Boiling water dissolves the mercuric salt more rapidly. A cold solution of potassium iodide readily dissolves the mercuric cyanide with the formation of the soluble double salt $Hg(CN)_2 \cdot 2KI$.

A series of experiments in which the masses of the interacting salts were varied proved that a compound of the two cyanides is formed, and suffers decomposition to a greater or less extent, depending on the relative amount of water present. An examination of the curves plotted from these results leads to the inference that the composition of the double salt is expressed by the formula $Zn_2Hg(CN)_{10}$, that is to say, the two cyanides are present in it in the proportion $Zn(CN)_2, \frac{1}{2} Hg(CN)_2$. Such a salt contains 40.6 per cent. of mercuric cyanide. It cannot be obtained pure, since it is decomposed by water, and it can only be produced by precipitation of aqueous solutions. Under the most favourable circumstances, when the quantity of water present is reduced to a minimum, a substance containing 98 per cent. of the double cyanide is obtained; the remaining 2 per cent. consists of zinc cyanide, resulting from the decomposition of some of the double salt by water,

the mercuric cyanide being dissolved, whilst the insoluble zinc cyanide remains mixed with the double salt. All attempts to prepare the double cyanide by other methods than that of precipitation have failed. Fundamental molecules of zinc cyanide and mercuric cyanide must apparently be present, in order that combination may occur. The aggregates of fundamental molecules $[Zn(CN)_2]_n$ and $[Hg(CN)_2]_m$, which constitute the solid salts, show no tendency to combine. No evidence is forthcoming of the existence of any other compound of the two cyanides than that now described. No similar compound of zinc cyanide with other metallic cyanides than that of mercury could be obtained.

This tetrazincic monomercuridecyanide, mixed with more or less zinc cyanide, has been found by Sir Joseph Lister to be an admirable surgical antiseptic, and it is at his suggestion that the inquiry was undertaken.

A full account of the best method of preparing the salt is given in the author's previous paper (J. Chem. Soc. Abstr. 1890, 855).

In the discussion following, Sir Joseph Lister said that the great value of the salt arose from the circumstance that while equally effective as an antiseptic, it had none of the irritant qualities of mercuric cyanide; and its slight solubility was an advantage. When mercuric chloride was used, it was liable, on the one hand, to be washed away by the discharges, and, on the other, to accumulate until a solution was formed which was so concentrated that it caused great irritation.

β -Pyridine and Piperidine Bases. C. Stoehr. J. Prakt. Chem. 1892, 45, 20—47.

By heating a mixture of glycerol and ammonium phosphate, β -methyl pyridine results, as has been shown by the experiments of P. Schwarz (Ber. 1891, 24, 1676) and of L. Storch (Ber. 1886, 19, 2456). The reaction is a complex one, and a number of basic products result in addition to the β -methyl pyridine, including β -ethyl and perhaps β -propyl pyridine; also a considerable quantity of pyridine itself is formed and bases containing 2 atoms of nitrogen, which are to be regarded as homologues of the diazine $C_4H_4N_2$. Only traces of α -pyridine bases result, which is of interest since the bases obtained from animal oils, the formation of which is to be traced to the glycerol of the fats in the animal residues, consist essentially of these α -bases. The mixture of bases obtained by the distillation of glycerol and ammonium phosphate boil between 120° C. and 250° C. The most volatile portion of the oil (up to 120° C.) contains the pyridine, that from 120° — 149° C. a mixture of pyridine and β -methyl pyridine together with a small quantity of α -methyl pyridine, and that from 140° — 150° C. the bulk of the β -methyl pyridine, which was isolated by means of its mercuric double chloride. The free base boils at 143° — 143.2° C., and has the sp. gr. 0.9748 at 0° C. It is soluble in water in all proportions on gentle warming, combines with methyl iodide to a crystalline ammonium iodide, which is readily soluble in water and is carbonised when heated with bromine. The base obtained by the distillation of strychnine and of brucine with lime is identical with the above in every respect. The platinum double chloride of β -methyl pyridine—

forms monoclinic crystals, which lose their water of crystallisation over sulphuric acid and melt with decomposition at 201° — 202° C. When gently heated, the salt gives up hydrochloric acid to form the platino-salt, $(C_6H_7N)_2PtCl_4$, a pale yellow crystalline precipitate, almost insoluble in water. The mercuric chloride double salt, $C_6H_7N \cdot HCl \cdot HgCl_2$, crystallises in needles from solutions containing 2—3 per cent. of free hydrochloric acid, and melts at 146° C. The zinc chloride and silver nitrate double salts, $2(C_6H_7N) \cdot ZnCl_2$ and $3(C_6H_7N) \cdot AgNO_3$, are also characteristic. β -methyl pyridine does not condense with aldehydes, differing in this from the isomeric α - and γ -bases.

On reduction with sodium amalgam in alcoholic solution, β -methyl piperidine, $C_6H_{12}N$, is formed. This is a

colourless oil, boiling at 125° — 126° C., and having a specific gravity of 0.8635 at 0° C. Its salts with mineral acids are characterised by being readily soluble in water, whilst the double salts are also considerably more soluble than those of the corresponding pyridine base.

β -ethyl Pyridine, $C_5H_4(C_2H_5)N$, is contained in the portion of the mixture got by the distillation of glycerol and ammonium phosphate, boiling at 160° — 166° C., and is best isolated by means of its mercuric double salt, which closely resembles the corresponding β -methyl pyridine salt, and which melts without decomposition at 131° — 132° C. The free base boils at 165° C., and has the sp. gr. 0.9585 at 0° . It is a colourless, highly refractive liquid, considerably less soluble in water than the methyl base, and readily volatile with steam. Its salts with mineral acids are very hygroscopic, but the base forms well-defined double salts with mercuric chloride, platinum chloride, auric chloride, silver nitrate, and with picric acid. On oxidation with potassium permanganate, nicotinic acid results. The base obtained by distilling hucine with lime, together with β -methyl pyridine, is β -ethyl pyridine, which is identical with the product from glycerol in every respect. β -ethyl pyridine forms a crystalline ammonium iodide, the cadmium iodide double salt of which is characteristic. On reduction β -ethyl pyridine, $C_5H_4(C_2H_5)NH$, is formed, which boils at 154° — 155° and has a sp. gr. 0.8711 at 0° C., the hydrochloride of which is readily soluble both in water and in alcohol. Other salts of the base are described. The physiological action of β -methyl- and ethyl pyridine was tried on white mice by subcutaneous injection, the bases being employed in the form of their hydrochlorides. They both act similarly to conine. The breathing is gradually slowed after being first stimulated, and this action is then followed by flowing of saliva and clonic spasms, finally producing death. The fatal dose is greater in the case of the methyl base, the relative intensity of the action as compared with that of conine being 7.1 to 1 in the case of β -methyl pyridine and 6.2 to 1 in that of β -ethyl pyridine.

Synthesis of Oxygenated Pyrazole Derivatives. L. Lederer. J. Prakt. Chem. 1892, 45, 83—94.

The synthetical methods employed for the preparation of antipyrine have led the author to study the action of phenylhydrazine in β -halogen substituted fatty acids. Condensation takes place between the amidohydrogen of the phenylhydrazine and the halogen atom of the substituted acid, an asymmetric derivative of the fatty acid with phenylhydrazine being first formed, which readily condenses to a pyrazolone from which an isomer of antipyrine can be prepared.

β -bromobutyric acid in the form of its potassium salt was employed as the starting point, and this when treated with phenylhydrazine yields asymmetric phenylhydrazine butyric acid.

This acid forms glittering plates when crystallised from alcohol, which melt at 111° C. and when heated with concentrated sulphuric acid to 100° C. yielded phenyl-methyl-isohydro-pyrazolone which can be extracted with chloroform after neutralising the product of the reaction with ammonia.

It forms colourless crystals which melt at 127° C. when crystallised from alcohol; from benzene solution it sometimes separates in an unstable form consisting of colourless crystals which readily change into a stable pale red-coloured modification. With silver nitrate a blue colour resembling Pyrazole blue is formed. When methylated a readily soluble product results, which tastes something like antipyrine. This substance is under investigation. A mono-acetyl derivative melting at 79° is easily obtained in the normal way. When oxidised with a dilute aqueous solution of ferric chloride, phenyl-methyl-isopyrazolone is formed, which is best extracted with chloroform. It is readily soluble in benzene, chloroform, and alcohol, and like the hydro-base exists in two modifications, the unstable form melting at 157° C., the stable form at 167° C. When heated in methyl alcohol solution in a sealed tube to 100° with an excess of methyl iodide phenyl-dimethyl-iso-pyrazolone the isomer of

antipyrine is formed, which is also extracted from alkaline solution by chloroform. Iso-antipyrine is readily soluble in water and in alcohol, soluble in chloroform and in hot benzene, difficultly soluble in ether. From the last it separates in tables which melt at 113° . It is a strong base closely resembling antipyrine in its behaviour with reagents. The platinum double chloride is more soluble in water than that of antipyrine, but both melt at the same temperature— 192° C. The picrate is, like that of antipyrine, with difficulty soluble in water; it forms pale yellow needles which melt at 168° C.; antipyrine picrate melts at 187° C. Potassium ferrocyanide gives a white crystalline precipitate in slightly acid solution of the base, ferric chloride gives a dark red colouration and bromine is absorbed by a glacial acetic acid solution of iso-antipyrine, a crystalline product separating on standing.

In all these reactions the base behaves just like antipyrine. The salicylate of iso-antipyrine is difficultly soluble in water and does not crystallise as readily as the corresponding salt of antipyrine. The dilute slightly acid solution is coloured emerald green by sodium nitrite, and in more concentrated solution a precipitate of the nitroso-body is formed which, when pure, consists of moss-green needles which decompose at 155° C. Like nitroso-antipyrine, this body gives Liebermann's nitroso reaction. Iso-antipyrine is less stable towards nitric acid than antipyrine; the nitro-compound formed melts at 210° C. Both antipyrine and iso-antipyrine melt at 113° and resemble one another exactly in their solubilities. They are both separated from their aqueous solutions on the addition of caustic soda as oils which are readily taken up by ether. Iso-antipyrine is also a powerful antipretic.

The constitutional formulæ for the two bases are:—

Iso-antipyrine.

(Phenyl-dimethyl-isopyrazolone.)

Antipyrine.

(Phenyl-dimethyl-pyrazolone.)

The reactions involved in this preparation have been patented in Germany, D. R. P. 53,834, October 1889.

—C. A. K.

Dextro-rotatory Terpene from the Leaves of the Siberian Cedar (Pinus sibirica). F. Hawitsky. J. Prakt. Chem. 1892, 45, 115—123.

The complete analogy in the properties and reactions of the dextro- and laevo-rotatory terpenes from both Russian and French turpentine oil render it highly probable that the rotatory powers of these two modifications of terpenes are equal and opposite although the laevo-rotatory terpene from French oil has a specific rotatory power $[\alpha]_D = -43.36^{\circ}$, and the dextro-rotatory terpene from Russian oil a rotatory power of only $+32.00^{\circ}$. The method of isolation of the terpenes from the two oils may explain this difference, but even when the latter was purified by distillation with steam and subsequent fractionation its specific rotatory power was only brought up to $+37.8^{\circ}$. The author has, therefore, examined the oil of the Siberian cedar with the view of obtaining a purer dextro-rotatory terpene. The purified terpene boils at 156° under 753 mm. pressure (corr.), and has a specific rotatory power $[\alpha]_D = +45.04$. It yields a crystalline hydrochloride $C_{10}H_{16}HCl$, which melts at 125° and a bromide, $C_{10}H_{16}Br$, which could not be obtained in a solid form. With alcoholic sulphuric acid a hydrate, $C_{10}H_{16}O$, boiling at 210° C. and possessing all the properties of the hydrate of dextro-rotatory terpene, results.

The chemical and optical properties of the above substances together with measurements of the latter are fully detailed in the paper, together with the method of isolation and purification of the oil.—C. A. K.

The Terpenes of the Oil from the Resin of the Pine (Pinus abies). B. Kuriloff. J. Prakt. Chem. 1892, **45**, 123—133.

The oil obtained from the resin of *Pinus abies* consists of an optically inactive terpene and a dextro-rotatory isoterpene. The former boils at 157° (corr.) under 760 mm. pressure and forms a hydrochloride, $C_{10}H_{16}.HCl$, melting at 126·5° C. The isoterpene, which forms about 2 per cent. of the oil, boils at 176·7° (corr.) under 772 mm. pressure and has a specific rotatory power $[\alpha]_D = -47·5^\circ$. Its hydrochloride, $C_{10}H_{16}.2 HCl$, crystallised from alcohol, melts at 48·5° C. The paper contains full details of the properties, densities and refractive powers of the two substances.

—C. A. K.

PATENTS.

Improvements relating to the Manufacture or Production of certain Phosphorus Compounds. P. G. W. Typke, New Malden. Eng. Pat. 2,252, February 7, 1891.

The phosphoretted hydrogen given off in the manufacture of the hypophosphites is recovered and converted into phosphorus according to the following process. The gases and steam evolved in the manufacture are first cooled and the greater portion of the steam thus condensed. The cooled gases are then led through tubes or retorts made of fireclay or of iron filled with pumice stone, coke, or other suitable material which will stand a high temperature and which will not combine either with phosphoretted hydrogen or with its decomposition products. The hydride of phosphorus is thus completely dissociated; the vapours of phosphorus are condensed in suitable receivers whilst the hydrogen is allowed to escape.—C. A. K.

Improvements in the Production and Separation of Methylamines, Ethylamines, Phenylamines, and Naphthylamines. R. Vidal, Paris, France. Eng. Pat. 3622, February 27, 1891.

See under IV., page 344.

Improvements in the Manufacture or Production of Orthoxydiphenyl-carbon Acid. B. Willeox, London. From F. von Heyden, Nachfolger, Radebeul, Germany. Eng. Pat. 5122, March 21, 1891.

See under IV., page 344.

Process for the Production of Mono- Bromo- and Di-bromo-para-ox-benzoic Acid, suitable for Conversion into Protocatechuic Acid, Pyrocatechin, and the like. J. Y. Johnson, London. From F. von Heyden, Nachfolger, Radebeul, Germany. Eng. Pat. 5184, March 23, 1891.

MONO-BROMOPARAHOXYBENZOIC acid is prepared by treating the free acid or its alkyl ester with one molecular proportion of bromine, in glacial acetic acid solution. The dibromo substitution product is obtained by the action of the calculated quantity of bromine on the alkyl esters of the acid dissolved in caustic soda. The free acid, when thus treated, yields tribromophenol.—C. A. K.

Improvements in the Formation of Ozone in presence of Air or Oxygen, and Apparatus therefor. A. Schneller and W. F. Wisse, The Hague, Holland. Eng. Pat. 5222, March 24, 1891.

See under XI., page 354.

Improvements in the Production of Salicylic-Acid Derivatives containing Chlorine and Sulphur. J. Y. Johnson, London. From F. von Heyden, Nachfolger, Radebeul, Germany. Eng. Pat. 5263, March 24, 1891.

DITHIO-SALICYLIC acid results when two molecular proportions of salicylic acid are treated with one molecular portion of chloride of sulphur ($S_2 Cl_2$) by the method

described in a previous patent (Eng. Pat. 14,443 of 1888). If double the above proportion of chloride of sulphur be employed, and the mixture heated to 100°—150° C. a mixture of derivatives of salicylic acid result more highly sulphurised than the dithio-salicylic acid, and which also contain a portion of the hydrogen substituted by chlorine. When not less than four molecular proportions of the chloride of sulphur to two of salicylic acid are used, a simple body results which from analysis appears to be a tetrathio-dichloro salicylic acid, having the following formula:—

The free acid forms a clear yellow amorphous mass, insoluble in cold water, readily soluble in ether, alcohol, &c. The alkali salts and the magnesium salt are readily soluble in water, whilst the salts with the heavy metals and with the alkaline earths are yellow to grey-coloured precipitates.

—C. A. K.

Improvements in the Manufacture of Aromatic Glycolol Derivatives. W. Majert, Berlin, Germany. Eng. Pat. 5269, March 24, 1891.

Two products have been shown to be formed by the action of ammonia on chloro- or bromo-acetanilide, viz.:—Glycolol anilide and di-glycolol anilide. These same bodies are formed when the esters of glycolol or glycolol amide are treated with a primary aromatic amine, according to the following equations:—

or—

The resulting products are readily soluble in water and alcohol, less soluble in ether, benzene or petroleum ether; the derivatives obtained from the di-alkylated primary amines are insoluble in water. They are all strong bases, which absorb carbonic acid readily from the air and combine with acids to form stable salts. The salts are decomposed by ammonia in the cold, but hot solutions of ammonium salts are decomposed by the free bases.

The di-glycolol derivatives are very weak bases and their salts dissociate in aqueous solution.

The products are best prepared by the action of alcoholic ammonia on bromacetanilide and its homologues, or by treating the methyl or ethyl ester or the amide of glycolol with the amine. In this way the following bodies have been obtained, the physical properties of which are described in the patent:—Glycololanilide, dimethyl glycololanilide, glycolol-toluide (ortho, meta, and para), glycololanisidine (ortho, meta, and para), glycolol-phenetidine (ortho, meta, and para), and glycolol-diphenylamine.—C. A. K.

Production of Basic Gallate of Bismuth. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, and Brüning," Hoechst-am-Maine, Germany. Eng. Pat. 6231, April 11, 1891.

NEUTRAL bismuth nitrate in nitric acid solution is treated with gallic acid dissolved in 70 per cent. alcohol and caustic alkali or alkali carbonate added to the resulting mixture until the whole remains but slightly acid. On the addition of sodium acetate or on dilution with water a yellow precipitate of basic bismuth gallate is formed, having the composition $Bi(OH)_2CO.O_6C_6H_2(OH)_3$. It is insoluble in water and in dilute acids. Neutral soluble salts of gallic acid may be substituted for the free acid in the preparation.

—C. A. K.

Improvement in and Relating to the Production of a Solution of Myrrhic Resin. W. P. Thompson, Liverpool. From A. Flügge, Frankfurt-on-Maine, Germany. Eng. Pat. 6306, April 13, 1891.

MYRRH is a gum resin containing about 30–35 per cent. of resin, 3 per cent. of ethereal oil, and 65 per cent. of gum. Hitherto strong alcohol has been the only known solvent for the resin, but the patentee finds that a solution of four parts of castor oil to one part of alcohol dissolves the resin completely when digested with it in a closed vessel for eight days. The solution obtained is perfectly clear, of a light brown colour and of an agreeable aromatic smell. A similar solution can be got by treating the alcoholic extract of the resin with castor oil and then evaporating off the former solvent. The solution can be diluted with other oils or fats, and can be employed for embalming and preserving purposes, which is not the case with alcoholic solutions of the resin, the resin being separated from the latter immediately on contact with water.—C. A. K.

Improvements in and relating to the Manufacture of Hydrazine or Diamidogen and its Salts. J. Y. Johnson, London. From the Badische Anilin und Soda Fabrik, Ludwigshafen, Germany. Eng. Pat. 6786, April 20, 1891. (Second Edition.)

THE preparation of hydrazine, $\text{NH}_2\text{—NH}_2$, starts from guanidine either in the form of thiocyanate or of carbonate which is converted into a nitro-compound by the action of nitric acid preferably in presence of sulphuric acid. The product of the reaction is poured into water, when the nitro-guanidine separates and may be purified by recrystallisation from water. Other salts of guanidine can be substituted for the above and nitrates can be employed in place of nitric acid. The nitro-compound is then reduced to the corresponding amido-guanidine, zinc-dust or iron filings in presence of dilute acid or else sodium amalgam being used. The solution of the resulting salt of amido-guanidine is then concentrated, and may be purified by converting it into the sulphate, which is difficultly soluble. By the action of alkalis, the hydrates of the alkaline earths, mineral acids or water under pressure, the amido-guanidine is decomposed with the liberation of ammonia and of carbon dioxide and the formation of hydrazine. This decomposition is effected in a vessel attached to an upright condenser. The hydrazine can be precipitated as sulphate by means of sulphuric acid, or it can be purified by other known means such as distillation and subsequent conversion into any desired salt.

Hydrazine is capable of use in the production of various chemical and pharmaceutical compounds.—C. A. K.

Improvements in the Manufacture of Iodine Substitution Products of Phenols and Cresols. B. Willeox, London. From the "Farbenfabriken vormals F. Bayer & Co.," Elberfeld, Germany. Eng. Pat. 7026, April 23, 1891.

By acting with iodine in presence of alkali on certain phenols the hydrogen atom of the hydroxyl group is replaced by iodine as already described in previous patents. (Eng. Pat. 5079, March 23, 1889, and Eng. Pat. 18,021, November 8, 1890; this Journal, 1890, 412.) The phenols previously employed were phenol, cresol, thymol, para-isobutylphenol, para-isobutylortho-cresol, and para-isobutylmeta-cresol. The present specification covers the preparation of similar products from ethyl, propyl, and amyl phenol, methyl, ethyl and amyl cresols and propyl cresols, isomeric with thymol and carvacrol. Amyl phenol is obtained by heating phenol amyl alcohol with zinc chloride and the other substituted phenols are similarly prepared by heating the phenol with the alcohol in presence of zinc chloride. The resulting phenol is separated by the addition of alkali and purified by fractional distillation after the addition of acid. The iodine derivatives are obtained by treating a solution of the phenol in alkali with a solution of iodine in potassium iodide, in the form of yellow amorphous precipitates. They give off

iodine in heating, are insoluble in water, but dissolve readily in olive oil, ether, and chloroform, somewhat less readily in alcohol, benzene and petroleum ether. Like the iodine derivatives previously described, these new products are used for medical purposes.—C. A. K.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

An Exact and Convenient Method for the Determination of Vapour Densities. C. Schall. J. Prakt. Chem. 1892, 45, 134–144.

THE method, which applies also to the determination of vapour densities under greatly reduced pressure, depends upon the measurement of the depression of a column of mercury placed in manometer produced by the vapour of the substance, this pressure being compared with that produced by the decomposition of a known weight of pure sodium carbonate when decomposed by dilute sulphuric acid. The apparatus consists of a three-bulbed vessel heated in a suitable bath and connected by a T-piece on the one hand to the manometer, and on the other hand to a tube leading to a pump. The substance is clamped between the two ends of a tube above the bulbed vessel previously to introducing it into the latter. The vessel for decomposing the sodium carbonate is attached to the tube leading to the manometer by a second T-piece. The whole apparatus is first exhausted, then the carbonate decomposed, and finally the substance introduced, measurements of the pressure exerted by the carbon dioxide in the first case, and by the vapour of the substance in the other being taken. The vapour density is then calculated according to the formula—

$$D = \frac{g \times h \times 106 \times 1.528}{h' \times G \times 44}$$

Where g = weight of substance.

G = weight of carbonate.

h = pressure due to carbon dioxide.

h' = pressure due to substance.

1.528 = specific gravity of CO_2 compared with air.

44 = molecular weight of CO_2 .

106 = molecular weight of Na_2CO_3 .

Full details of the method, together with a sketch of the apparatus, are given in the paper.—C. A. K.

INORGANIC CHEMISTRY.— QUANTITATIVE.

The Solubility of Sodium Carbonate and of Sodium Bicarbonate in Solutions of Sodium Chloride. K. Reich. Monatsh. 1891, 12, 464–473.

See under VII., pages 346–347.

The Quantitative Determination of Arsenic by the Berzelius-Marsh process, especially as applied to the Analysis of Wall Papers and Fabrics. C. A. Sanger. Amer. Chem. J. 1891, 13, 431–453.

THE object of the author was to obtain some method by which a very small amount of arsenic might be estimated without resorting to the usual quantitative methods which require too much time for ordinary use.

The author's method of obtaining an approximate estimate of the amount of arsenic present was suggested by H. B. Hill, and consists, briefly, in the comparison of the

mirror obtained from an aliquot part of the solution with a series of standard mirrors obtained from known weights of arsenious oxide.

A known quantity of the paper is taken, the quantity depending upon the probable quantity of arsenic present, and upon the character of the paper (*i.e.*, whether a plain colour, a small or large pattern). The paper is measured by means of thin glass plates cut to the required dimensions. The author has used the following sizes:—25 sq. cm. (5×5); 50 sq. cm. (5×10 , 4×12.5 , 2×25); 100 sq. cm. (10×10 , 5×20 , 4×25 , 8×12.5 , 2×50).

The paper is cut into small pieces and treated in a glazed porcelain dish with strong sulphuric acid (1 to 5 cc.), to which has been added about one-thirtieth of its volume of strong nitric acid. When the paper has absorbed the acid, the dish is heated over a low flame until the paper is thoroughly charred, the mixture being continuously stirred with a thick glass rod. In order to get rid of every trace of nitric acid it is best on cooling to add a few cc. of water, and heat again until sulphuric acid fumes appear. On again cooling the "char" is moistened with about 5 cc. of water, well triturated with the glass rod until all lumps are thoroughly broken up, heated to boiling to expel sulphur dioxide, and filtered hot, which is best done by means of a filter-pump. After filtering the "char" is washed with hot water, and after cooling the extract is ready for weighing and introduction into the apparatus.

Any form of hydrogen generator may be used, but the author prefers to use a modification of Bloxam's electrolytic method, in order to ensure a constant supply. To the delivery-tube is attached a two-way or a three-way distributing tube according to the number of reduction flasks to be used. The reduction flask is a wide-mouthed bottle of about 75 cc. capacity, fitted with an india-rubber cork pierced with three holes. Through one hole passes a right-angled tube reaching to the bottom of the flask, the other end being connected to the distribution tube of the generator. Through the second hole is inserted the right-angled delivery tube, reaching just below the cork, and the third hole serves for the introduction of acid and extract. A straight bulb drying-tube containing calcium chloride is attached to the delivery-tube of the reduction-flask, and to this drying-tube is attached the reduction-tube of hard Bohemian glass. At the place where the arsenic mirror is formed this tube is drawn out till the bore is from 1.5 mm. to 2 mm. This finely drawn part is bent slightly upward and sealed.

The reagents and materials employed must be strictly free from arsenic and the acid should be one part strong acid in eight parts of water. In the reduction-flask are placed not more than three grms. of zinc and about 20 cc. of acid. The hydrogen is now turned on from the generator, and lighted, the flame being not more than 1 to 2 mm. in height, the evolution of hydrogen being kept at this rate during the reduction. If the flask becomes heated it may be placed in a basin through which a current of cold water circulates. Before adding the extract the author allows the hydrogen to run for about 15 or 20 minutes to test for arsenic, a lamp being held under the heating place. If the apparatus is found free from arsenic a known portion of the extract is added. If no mirror appears in three or four minutes a further quantity is added, and the whole may be introduced if no mirror appears in another five minutes. When the size of the mirror formed in the first 15 minutes is not larger than that corresponding to 0.05 mgrm. of arsenious oxide, 25 minutes is sufficient for the deposition of all the arsenic.

To make the standard mirrors the author takes 1 gm. of pure arsenious oxide dissolved in water by means of sodium bicarbonate and acidulated with sulphuric acid. This is then made up to a litre and contains 1 mgrm. of As_2O_3 to 1 cc. Ten cc. of this solution are then made up to a litre forming a second solution containing 0.01 mgrm. to 1 cc. Of this, 1 cc., 2 cc., 3 cc., &c. are carefully measured into the reduction flask, giving mirrors corresponding to the same number of hundredth-milligrammes. Mirrors corresponding to half-hundredths may be made in order to get a complete set.

For the purpose of comparison the author uses a tin box shaped like a stereoscopic camera and painted black inside. The standard mirrors are mounted, in order, on a suitable slide, so that any pair of mirrors can be brought under the eye-holes. The mirrors to be compared are also mounted on a slide which can be inserted in the box above the first, thus allowing each mirror to be brought between a pair of the standard mirrors for comparison. The calculation of the amount of arsenic in the area taken follows from the determination of the amount in the aliquot part of the solution. From this can be found the number of milligrammes per square metre or of grains per square yard.

The following table shows a comparison of the results obtained by this method with those obtained by the volumetric method:—

Number of Paper.	Mgmm. As_2O_3 per Square Metre.	
	Barz-Marsh.	Volumetric.
363	8.8	9.1
359	24.0	29.5
392	43.8	40.5
39	64.9	67.5
405	72.8	71.9
111	110.4	108.7
395	133.0	210.4
42	178.8	121.8
194	842.0	832.7
155	1527.1	1478.5

This table shows that the method not only gives an approximation to the actual amount, but may be made with care to give results comparable with those of other quantitative methods.

The author thinks the process likely to be of great use in toxicological work, being the only means of rapidly estimating the amount of arsenic present when this is minute, the arsenic being extracted by distillation. The limit of arsenic that he has been able to detect by this method is 0.001 mgrm. As_2O_3 or 0.0007 As.—D. E. J.

The Volumetric Estimation of Mercury. Chapman Jones, Proc. Chem. Soc. 1892 [108], 46—47.

THE author has found the cyanide method of estimating mercury suggested by Hannay (J. Chem. Soc. 1873, 565) and modified by Tuson and Neison (J. Chem. Soc. 1877, 32, 673) to be unsatisfactory, the presence of carbon dioxide interfering with the titration. If, however, instead of adding the potassium cyanide solution until the turbidity produced by ammonia disappears, the titration be finished by adding, with certain precautions, a standard mercury solution until a definite and permanent turbidity is produced, concordant results are readily obtained. The method of working described is, if necessary, to separate the mercury as sulphide, and dissolve the washed precipitate in cold *aqua regia*, and to dilute and filter the solution. For the titration, litmus extract is added and neutralisation effected with solid potassium carbonate and hydrogen chloride, and finally with dilute ammonia. Excess of the cyanide solution is added, then a slight excess of ammonia, and, lastly, a standard solution of mercuric chloride, until a permanent turbidity is obtained, equal to that produced by 0.1 cc. of the mercury solution in water containing about the same amounts of litmus and ammonia as the solution which is being titrated.

ORGANIC CHEMISTRY.—QUANTITATIVE.

Sulphocyanogen in Coal-Gas. J. V. Esop. Chem. Ind. 1892, **15**, 6-10.

See under II., pages 337-338.

The Composition of Turkey-red Oil. P. Juillard. Bull. Soc. Chim. 1891, **6**, 638-656.

See under XII., pages 355-357.

Report Pharmaceutical Conference, Halle. Chem. Zeit. 1891, **15**, 1371-1376.

AMONG several papers read by Soltsien the following will no doubt be found very interesting:—

1. *Detection of Unsaponifiable Fats.*—The process recommended consists in treating with sulphuric acid and shaking out with petroleum spirit.

2. *Detection of Nitric Acid in Vinegar.*—The tests with brucine or diphenylamine should always be applied before giving an opinion.

3. *Cinnamon Powder.*—The author calls attention to the enormous dilution with sugar.

4. *Mace.*—This is still adulterated wholesale with the inferior Bombay article, and to improve it again a little of a small proportion of nutmeg is added. It is a pity that there exists as yet no reliable chemical test, so the expert must rely on the microscope.

5. *Cocoa.*—This is mixed to such a large extent with shells and starch that it is often undeserving of the name.

—L. de K.

On the Nitrogenous Bases present in the Cotton Seed. W. Maxwell. Amer. Chem. J. 1891, **13**, 469-471.

Owing to the known poisonous character of choline the author has endeavoured to find out whether choline and betaine are present in the cotton seed from which various cattle foods are prepared, both these alkaloidal principles having been shown to be present in the foods. 0.3 grm. of choline is sufficient to paralyse a strong cat and 0.5 grm. will produce immediate death. Betaine is generally believed to be non-poisonous, but is usually found admixed with choline. It is, therefore, very desirable to estimate the quantities of these bodies present in cotton seed.

About 5 lb of finely-ground cotton-seed cakes are extracted with 70 per cent. alcohol, the extract distilled and the residue taken up in water. On adding lead acetate to this solution, a lead precipitate is thrown down which is separated by filtration, and the filtrate is evaporated to a syrup after the excess of lead has been removed from it. The alkaloidal bodies are then taken up from this syrup in a mixture of 70 per cent. alcohol and 1 per cent. hydrochloric acid. This extract is treated with an alcoholic solution of mercuric chloride, and immediately an almost pure white double salt of the nitrogenous bases begins to separate out. After standing for 10 days the crystals are separated from the liquid, from which more crystals can be obtained after some weeks. After recrystallisation from water the salt is decomposed by means of hydrogen sulphide, the mercury sulphide being removed by filtration. The filtrate containing the hydrochlorides of the bases is slowly evaporated to a small volume, and then placed in a desiccator over sulphuric acid until crystallisation of the salts is complete. The crystals are free from colour and well-developed. After drying they are saturated with absolute alcohol in which the choline salt dissolves along with a small proportion of the betaine salt. 7.248 grms. of the crystals were treated with alcohol, and the extract evaporated to dryness and re-extracted three times to obtain the choline salt free from betaine. The following were the results:—

Choline hydrochloride = 1.08 grms.
Betaine " = 6.168 grms.

Choline and betaine appeared to be present in the sample of cattle food used by the author in the relative proportions of 17.5 per cent. choline to 82.5 per cent. betaine.

The alcoholic solution of the choline salt was treated with platinum chloride, and a platinum double salt of choline obtained. From this an aqueous solution of choline hydrochlorate was obtained by treatment with hydrogen sulphide, and the separation of the resulting sulphide by filtration. This aqueous solution gave the following reactions:—

- With (1.) Phospho-tungstic acid, white precipitate.
- (2.) Phospho-molybdic acid, yellow precipitate.
- (3.) Bismuth-potassium iodide, red precipitate.
- (4.) Cadmium-potassium iodide, grey precipitate.
- (5.) Iodine, brown precipitate.
- (6.) Platinum chloride, yellow precipitate soluble in water.

An aqueous solution of the betaine salt was treated with phospho-tungstic acid and a phospho-tungstate of the base obtained. This was broken up with calcium hydroxide and the resulting lime salt filtered off. The residue was extracted with strong alcohol from which free betaine was crystallised out.—D. E. J.

An Error in the Determination of Albuminoid Nitrogen by Kjeldahl's Method. H. Synder. J. Amer. Chem. Soc. 1891, **13**, 212-214.

In the determination of nitrogen by Kjeldahl's method, all the mercury should be precipitated by potassium sulphide in order to prevent the formation of mercurammonium compounds which resist the subsequent action of soda. The "official" modification of this process requires, however, for the determination of albuminoid nitrogen the use of 7-8 grms. of copper hydroxide, which is also precipitable by potassium sulphide; as the quantity of sulphide employed is never sufficient to precipitate the whole of the copper and mercury, a large and variable portion of the latter metal is left in the solution, and all the conditions are favourable for the formation of mercurammonium compounds. This was confirmed by experiment, lower results being obtained when an amount of potassium sulphide insufficient to precipitate the total copper and mercury was used, than when an excess was employed. The author recommends the following modification of the "official method":—7 grms. of the substance, a quantity of copper hydroxide and glycerin solution equivalent to 0.5-0.6 grms. of the hydroxide, and finally 30 cc. of potassium sulphide solution are used. In determining nitrates by the "official method" 2 grms. of zinc-dust are used, but to insure uniform results, the previous addition of 2 grms. of salicylic acid, to convert the zinc into an insoluble and crystalline form at the close of the digestion, is necessary.

—A. R. L.

The Specific Rotatory and Cupric Reducing Power of Invert Sugar and of Dextrose obtained from Cane Sugar by Means of Invertase. J. O'Sullivan. Proc. Chem. Soc. 1892 [109], 56.

AFTER referring to the various values assigned to the rotatory power of levulose and to the doubt thrown on Dubrunfaut's value by the statements of Herzfeld, Bornstein, and Winter, the author minutely describes experiments in which hydrolysis of cane sugar was effected by invertase instead of by means of acid. The conclusion finally arrived at is that, as the specific rotatory power of invert sugar obtained by means of invertase, which has no action on levulose, is $[\alpha]_D = -24.5^\circ$, and that of the dextrose prepared from such invert sugar is $[\alpha]_D = 57^\circ$, the apparent specific rotatory power of levulose calculated from these numbers must be $-24.5 \times 2 + 57^\circ = [\alpha]_D = 106$ or $[\alpha]_D = 93.8$, a value agreeing with that generally accepted.

New Books.

A TREATISE ON CHEMISTRY. By Sir H. ROSCOE, F.R.S. and C. SCHORLEMMER, F.R.S. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives, or Organic Chemistry. Part VI. London and New York: Macmillan & Co. 1892.

This part of Roscoe and Schorlemmer's well known and classical Treatise on Organic Chemistry, contains a description of the derivatives of naphthalene and the allied hydrocarbons, as well as of the compounds consisting of two or more benzene nuclei directly connected. It forms a volume of 8vo. size, bound in cloth, containing Preface, List of Contractions, Table of Contents, and 561 pages of subject-matter. The Alphabetical Index, a most complete one, occupies 18 pages. The text throughout is profusely annotated with references to original sources of information. The groups treated of are the following:—Indene Group. Naphthalene Group; Methyl-naphthalene Group; Dimethyl-naphthalene Group; Ethyl-naphthalene Group; Naphthalene Derivatives containing more than 12 carbon atoms; Naphthindole derivatives; Acenaphthene Group; Pyrene Group; Diphenyl Group; Methyl-diphenyl Group; Dimethyl-diphenyl Group; Ethyl-diphenyl Group; Derivatives of Diphenyl containing more than 14 carbon atoms; Azo Dyes of the Diphenyl Group; Fluorene Group; Phenanthrene Group; Retene Group; Fluoranthene Group; Phenyl-naphthalene Group; Chrysene Group; Dinaphthyl Group; Diphenylbenzene Group; Triphenylbenzene Group. Special attention is throughout the work given to the organic colouring matters and dyestuffs and their effects in dyeing and printing; also to those organic substances which may be classed as "Fine Chemicals." With regard to the technological application of organic substances in the tinctorial arts and pharmacy, &c., this work on Organic Chemistry throughout holds a perfectly unique position amongst treatises on this branch of science.

The price of the volume is 21s.

LESSONS IN ELEMENTARY CHEMISTRY, INORGANIC AND ORGANIC. By Sir HENRY E. ROSCOE, LL.D., F.R.S. Late Professor of Chemistry in the Victoria University, The Owens College, Manchester. London and New York: Macmillan and Co. 1892.

This well-known little work in this its latest edition, is considerably improved and enlarged. Especially in the section dealing with Organic Chemistry are the extensions noticeable. The last edition was published in 1886. In the Inorganic Chemistry Section, as an example of the stage to which this branch of the elementary literature has been brought, may be mentioned the record of the striking discoveries of nickel carbon monoxide and iron carbon monoxide made by Mond, Langer, and Quincke, and Mond and Quincke, respectively. In the Organic Chemistry Section it is noticeable that on the subject of Indigo, the chemistry of which has been deeply studied in so many phases for the main purpose of commercial application, the literature is naturally expanded, though notice of the technical application so far as replacement of the natural product is concerned, is in this edition cut down to the remark that "none (of the synthetical methods) have yet been so successful as to compete to any extent with the natural product."

Among the alkaloids, a short description of Cocaine and its uses, and of Antipyrine, with the constitution of the latter, is noted as an additional feature. Moreover a chapter is added (Lesson XLIII.) on the "Synthetical Production of Organic Compounds," in which the outlines of the more typical cases of Organic Chemical Synthesis are given. The present edition thus contains 43 chapters, whilst that of 1886 contained 41. The other additional chapter was obtained by splitting up Chapter XL. of the 1886 edition, on Turpentine, Camphor, and the Alkaloids, into two

chapters for this the 1892 edition, so that here we have Chapter XL. devoted to Turpentine, Camphor, and the Glucosides, whilst in Chapter XLI. the Alkaloids are separately dealt with. In the edition for 1886 there are 439 pages; in this the 1892 edition 486 pages of subject-matter. The work is illustrated with 78 well-executed wood engravings, and a beautiful chromolithograph chart of the spectra of the metals of the alkalis and alkaline earths. The price of the book is 4s. 6d.

ANLEITUNG ZUR CHEMISCHEN ANALYSE ORGANISCHER STOFFE. Von Dr. G. VORTMANN, Privatdocent an der Technischen Hochschule in Aachen. Leipzig and Vienna: Franz Deuticke. London: H. Grevel and Co., 33, King Street, Covent Garden. 1891.

IN his preface the author points out that hitherto the term "Organic Analysis" has been made almost exclusively and with few exceptions to refer to certain restricted methods of elementary quantitative analysis, and that the behaviour of organic substances to reagents, and especially of chemically allied substances to one and the same reagent, has received but scanty attention of a systematised kind. But the means at disposal through lack of systematised matter, and by reason of many vacancies as to known reactions, were inadequate, and much special experimental investigation was necessary before the vacancies could be filled up and a definite system constructed. This work now contains a system of qualitative reactions. The author states that he has not given much prominence to the treatment of the alkaloids, as this subject is already so well handled in the text-books of analytical chemistry.

The present volume is of 8vo. size, with paper cover, and containing Title page, Preface, Table of Contents, subject-matter covering 403 pages, and an Alphabetical Index. Lastly follows a series of 18 elaborate tables of numerical data of which the principal comprise "Vapour Tensions of Potash Solution of 1.258 Specific Gravity;" "Melting and Boiling Points of the Hydrocarbons;" "Tables for Determining the Percentage Amounts of Alcohol in Spirituous Liquors;" "For Determining the Amounts of Alcohol by the Drop Test (Tranbe);" and "For the Specific Gravity and Index of Refraction of Aqueous Glycerol Solutions;" "Tables of Absorption Spectra;" "Specific Gravity of Mixtures of Ether and Alcohol (Squibb);" "Specific Gravity, Melting Points and Solidifying Points of Fats and Oils;" "Melting Points and Solidifying Points of Free Fatty Acids," &c., &c.

The text is illustrated by 27 wood-cuts representing apparatus necessary in the experiments.

The following excerpt of contents will sufficiently indicate the nature and scope of the work:—

I. *Detection, Discrimination and Quantitative Estimation of the Elements.*—A. Qualitative Analysis. Carbon. Hydrogen. Chlorine, Bromine, and Iodine. Oxygen. Sulphur. Nitrogen. Phosphorus. Metals. B. Quantitative Analysis. Estimation of Carbon and Hydrogen. Estimation of Chlorine, Bromine, and Iodine; of Oxygen; of Sulphur; of Nitrogen; of Phosphorus; of Metals. Methods for simultaneous Estimation of several Elements. Calculation of Analyses.

II. *Discrimination and Quantitative Estimation of Atomic Groups.*—Hydroxyl-, Methoxyl-, Ethoxyl-, Sulphohydryl-, Sulphomethyl-, and Ethyl-, Amido-, Imido-, Methyl-amido- or Ethylamido-, Hydrazine-, Diazo-, Nitro-, Nitroso-, Carbinol-, Aldehyde-, Carbonyl- (Ketone-), Carboxyl-, and Nitrile- Groups. Also Radicals of Hydroxy Acids.

III. *Discrimination and Quantitative Estimation of Compounds.*—Hydrocarbons. Halogen Substitution Products of the Hydrocarbons. Alcohols. Phenols. Ethers and Esters. Aldehydes. Ketones. Carbohydrates. Quinones. Glucosides. Acids. Sulphur Compounds. Primary Amines. Secondary Amines. Tertiary Amines. Acid Amides. Pyridine- and Quinoline- Bases. Alkaloids. Nitriles. Nitro Compounds. Albuminoids. The price of work is 10s.

HANDWÖRTERBUCH DER PHARMACIE. Praktisches Handbuch für Apotheker, Ärzte, Medicinalbeamte und Drogisten. Herausgegeben von A. BRESTOWSKI. Wien und Leipzig: Wilhelm Braumüller. K. U. K. Hof- und Universitäts-Buchhändler. London: H. Grevel and Co., 33, King Street, Covent Garden. 1892.

THIS, the second number of the new Dictionary of Pharmacology, edited and published by Brestowski, has just appeared. (See this Journal, 1892, 275, col. 1.) The price of each number issued is 2s. 5d. The Editor is assisted by 41 contributors of eminence. The first volume of the two which furnish the complete work will comprise about 24 numbers or parts.

Whilst due attention is given to the chemical relations and properties of the individual substances treated of in the text, the physiological and toxicological relations are specially dealt with, as also the best methods of preparation from the pharmaceutical point of view. Attention is also fully devoted to tests for purity and discrimination. The present number commences with *Amylacetate* and ends with *Aseptol* (*Orthophenolsulphonic acid*).

CHEMISCH-TECHNISCHES REPERTORIUM. Uebersichtlich geordnete Mittheilungen der neuesten Erfindungen, Fortschritte und Verbesserungen, auf dem Gebiete der Technischen und Industriellen Chemie mit Hinweis auf Maschinen, Apparate und Literatur. Herausgegeben von Dr. EMIL JACOBSEN. Erstes Halbjahr. Erste Hälfte. Berlin: R. Gaertner's Verlagsbuchhandlung. Hermann Heyfelder, S.W., Schönebergerstr. 26. London: H. Grevel and Co., 33, King Street, Covent Garden. 1892.

THIS, the first issue of Jacobsen's Repertorium for 1891, and representing the first half of the opening half year, appears in a volume, the pages of which run from 1 to 152. The text is illustrated with 27 woodcuts. The subjects treated of are as follows:—Building Materials, Cements, Artificial Stone, Colouring Matters, Dyes and Calico Printing, Fats, Oils, Illuminating and Heating Materials, Fermented Liquors, Tanning, Leather, and Glue Manufacture, Textiles, Glass, and Earthenware, Wood and Horn, India-rubber, Cements, Gums, Pastes, and Adhesives, Lakes, Varnishes, and Paints. Metals.

A DICTIONARY OF THE COAL-TAR COLOURS. Compiled by GEORGE H. HURST, F.C.S. (member of the Society of Chemical Industry). London: Heywood and Co., Lim., 68, Fleet Street. 1892.

LARGE 8vo. volume, handsomely bound in blue cloth and gilt. It contains Preface, a Plan of the Work, Introduction, and Text covering 106 pages. The matter is arranged alphabetically according to the technical or trade names of the colours. After each colour or dye is given in brackets the name of the manufacturer or inventor. The English patents are also given, number and year being specified. Modes of application of the colours, specialities, and tests are also included. Where several names are applied to a colour, these names are indicated. The method of treatment of each colouring matter described in this Dictionary may be gleaned from the following plan followed in each case as nearly as possible. "No systematic account of the process of manufacture or chemical relationships of the colours is given, but as far as possible to obtain the information, the chemical composition, formula, method of preparation, date of introduction, literature relating to it, and the discoverer are given, whilst the properties and uses of the colours have had special attention paid to them." The price of the work is 10s. 6d.

SILK DYEING, PRINTING, AND FINISHING. By GEORGE H. HURST, F.C.S., Lecturer on Technology of Painters' Colours, Oils, and Varnishes at the Manchester Technical School, &c. London: George Bell and Sons, York Street, Covent Garden; also New York. 1892.

SMALL 8vo. volume, bound in cloth. It contains Title Page, Preface, Table of Contents, List of Coloured Patterns, and 220 pages of subject-matter. The work terminates with an Alphabetical Index. The text is illustrated with 21 woodcuts and 11 plates of dyed and printed silk specimens. The subject-matter is divided into chapters, as follows:—I. Origin, structure, composition, and properties of Mori, Tussah, and other wild Silks. II. Boiling off and bleaching of Silks. III. Dyeing Blacks on Silk, Logwood blacks, and Tannin blacks, Aniline and other Coal-Tar blacks. IV. Dyeing of Fancy Colours on Silk. Weighing of Silks. Reds, Oranges, Yellows, Blues, Greens, Browns, Violets, &c., on Silk. V. Dyeing mixed Silk Fabrics. VI. Silk Printing. VII. Silk Dyeing and Finishing Machinery, Yarn Dyeing, Piece Dyeing, Silk Finishing Machinery, Silk Finishing. VIII. Examination and Assaying of Raw and Dyed Silks.

Appendix of 170 recipes for Dyeing and Printing Silks and 66 patterns.

The price of the book is 7s. 6d.

This book forms one of the Technological Handbooks, edited by Sir H. Trueman Wood, Secretary of the Society of Arts.

ZEITSCHRIFT FÜR ANORGANISCHE CHEMIE. Unter Mitwirkung von Berthelot, Blomstrand, Brauner, Clarke, Classen, Clève, Cooke, Cossa, Crookes, Ditte, Friedheim, Gibbs, Hempel, Joergensen, Krant, Lunge, Mallet, Mauro, Mendelejeff, Meyer, Mond, Nilson, Piccini, Roscoe, Seubert, Spring, Thorpe, Winkler, und andere Fachgenossen. Herausgegeben von GERHARD KRÜSS. Band I. Heft 1, 1892. Hamburg and Leipzig: Verlag von Leopold Voss. London: H. Grevel & Co., 33, King Street, Covent Garden.

THIS new and important work on Inorganic Chemistry is to appear as a periodical, the parts of which can ultimately be bound to form volumes of 30 sheets each. A volume would be priced at 12s. As the above eminent names indicate, the contributors to this work are of various nationalities and of representative character.

The present, and opening number, is a pamphlet of 8vo. size, containing 82 pages of subject-matter. The articles contributed to this the first issue are as follows: On Phosphorus Oxy-sulphide (Thorpe and Tutton). The Double Acids of the Heptatomic Iodine (Blomstrand). Action of Hydrogen Peroxide on some Fluorides and Oxyfluorides (Piccini). Some Ammoniacal Platinum Compounds (Carlgren and Clève). Preparation of Tungstates free from Molybdenum (Friedheim and Meyer). A Lecture Experiment (Winkler).

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

NEW SPANISH CUSTOMS TARIFF—Concluded.

Statement showing the Rates of Import Duty to be levied in Spain under the New Spanish Tariff, compared with the Rates of Duty hitherto leviable on Imports into that Country.

Note.—Up to the 30th June next, when the Anglo-Spanish Convention of 1886 expires, the Conventional rates of the Spanish Tariff will still be levied on British produce, including those of the Franco-Spanish and German-Spanish Treaties which are enumerated in Parliamentary Paper, Commercial No. 13 (1886). (C.—4779).

No.	CLASSIFICATION OF ARTICLES.	Rates leviable by New Tariff of 1st February 1892.		CLASSIFICATION OF ARTICLES.	Rates leviable hitherto on Imports from United Kingdom.
		General Tariff.	Special Tariff.		
	CLASS X.	Pes. cts.	Pes. cts.		Pes. cts.
	ANIMALS AND ANIMAL PRODUCTS EMPLOYED IN INDUSTRY.				
	Group 1.—Animals.

9	Ceylon cinnamon.....	8	00
10	Chinese cinnamon	2	00
11	Cloves	3	50
12	Pepper	3	50
13	Tea.....	4	00

Notes.

(1.) Coal and coke shall be cleared in conformity with the weight of the quantity received on board, stated in a certificate to be given to the captain of the vessel by the Spanish Consul at the port of loading, in accordance with the cargo note and bills of lading, which the said Consul shall demand to see for the purpose. In doubtful cases the Custom houses may verify the weight of the coal or coke.

(2.) Crude shale oils shall be understood to be those obtained by a first distillation, and distinguished by their yellow colour and their density of 0.900 to 0.920, or 66 to 57½ of the centesimal areometer, equal to 21.69 to 21.48 Cartier.

Crude natural mineral oils shall be recognised by the following qualities:—

1. That when gradually and continuously distilled in a glass vessel at a temperature of 300 C., they shall leave a residue of more than 20 per cent. of the original weight.

2. That this residue shall afterwards leave a minimum of 1 per cent. of coke of the total weight of the mineral oils assayed.

3. That when assayed in the Granier apparatus they shall be inflammable at a temperature of less than 16° C.

All mineral oils which have not the above properties shall be considered refined oils.

The duties imposed on mineral oils, whether crude or refined, are appraised on the net weight of the liquid.

Bottles ("envases") containing the said oils shall pay separately; barrels as casks; tin boxes as tin worked up; and wooden boxes in which the latter are inclosed as common wood worked up.

In all cases where doubts arise regarding the application of Nos. 7, 8, and 9, the Custom houses shall consult the Central Custom House (Dirección General de Contribuciones Indirectas).

As regards crude mineral oils, it shall be indispensable in all cases to take samples in the following form:—

In all clearing of crude mineral oil, a sample of 200 cubic centimetres shall be taken from every 50 cases, and a like quantity from every 10 barrels of the total quantity declared, provided the quality is the same.

These samples shall be mixed together in a large bottle, and when the clearance of the whole cargo has been effected, two litres shall be taken of the samples filling two bottles, and when these bottles have been closed with sealing wax and stamped, the labels shall be signed by the Customs officers and the owner of the goods, and the samples shall be sent on to the Director-General of Customs to be assayed.

The declaration shall be proceeded with at once in accordance with No. 8, and the owner of the goods shall be bound by the result of the analysis, and the clearance shall not be deemed definitive until that result be known.

The samples shall be assayed within the space of one month, no extension of this period being permissible. The owners of the goods shall have the right to see the samples opened and assayed, and to appeal to the Ministry of Finance from the decision of the Custom house.

When the owners of the goods request in their appeals that fresh assays be made, they shall be liable for the expenses thereof, should no change be required to be made in the clearance dues decided on by the Custom house. Should the contrary be the case the expenses shall be borne by the Administration.

In order to secure their right to be present at the clearance, owners of goods must demand this in writing when signing the labels of the samples.

3. See Tariff No. 4 respecting arrivals from non-European ports.

4. Under this number shall be comprised bottles, demi-johns, and flasks for holding oils, wines, drugs, perfumery, and chemical products, provided they be not cut; also thick unpolished glass of more than 12 millimetres, for skylights and pavements.

5. Under this number shall be comprised bottles, tumblers, glasses, and other articles for table service or lighting purposes, whether of crystal or glass, plain or stained.

6. Only rough bricks, flagstones, and tiles of baked earth or clay, employed in the construction of walls, furnaces, &c., are to be included in this category.

7. No. 17 includes small bricks for flooring and for mosaic work, and also the objects comprised under No. 16, employed for building, when glazed, painted, enamelled, and made of washed and sifted earths.

8. The articles of fine earthenware included in this category are dinner services and kitchen utensils.

19. The number of threads comprised in the inch for the application of this duty are only those of the warp of the stuff.

20 and 21. To test gilt articles, they shall be rubbed with hot alcohol, and then touched with a drop of nitric acid. If they are varnished only, the varnish will come off with the alcohol and the nitric acid will act; if they are gilt the alcohol will cause no corrosion and the nitric acid will not have any effect upon them.

Silvered articles shall be filed until the superficial coating of silver gives way, and the colour of the metal of which they are principally composed becomes visible. Moreover, if a portion of the plated metal be dissolved in nitric acid, the silver (if there be any) will be precipitated with chloric acid, thus forming chloride of silver soluble in ammonia and possessing the characteristics of this substance.

In the case of nicked objects, the superficial part of the nickel which overlays them shall be filed so as to leave uncovered the brass or other metal which forms their chief component.

22 and 23. See Tariff No. 4 on arrivals from non-European countries.

24. The colours comprised in this number are compounds having a metallic basis, and are used mixed, with oil or turpentine, generally insoluble in water, alcohol, or ether, rarely crystallised, and almost always in powder or lumps. Among these are white lead, yellow chromate, vermilion, Prussian blue, Thenardite, English green and parrot green ("papagayo").

25. The colours comprised in this number are called artificial colours or organic products in which metallic substances are rarely found. They are generally crystallised, soluble in water, alcohol or ether, and are used more for dyeing and stamping than in painting, with or without goldsize ("mordiente"). Among these are picric acid, aldehyde green, English violet, rose aniline, and salts of the same colours of naphthaline, artificial alizarine, &c.

26. The products or substances comprised in Nos. 118 and 119 shall be examined by pharmaceutical inspectors, who shall sign the certificates in conjunction with the Customs officials in the following form:—

The products cleared are correctly stated in the declaration and are or are not—passed as imports, the formula thereof having been published (state where); and the composition thereof having been ascertained by means of an assay made by A. B.

39. In order to have the benefit of this number the pulp or paste must be perforated so that it cannot be used for any purpose except paper making. When the paste or pulp is presented for clearance without being perforated, the Customs officers shall, at the expense of the owner of the goods, break up the sheets in a manner that may render the stuff useless for any other purpose than paper making. Paste or pulp not perforated shall pay duty as if it were common pasteboard.

42. Boxes of pasteboard lined with paper more or less common, that may be used as packing for handkerchiefs, shirt fronts, buttons, pieces of tissues, or other similar articles, shall pay duty in accordance with this number.

45. See Tariff No. 4 on arrivals from non-European countries.

70. Under this number are comprissed all tissues, whether they have one or two coatings of rubber, and likewise those which are rubbered only between the two surfaces.

GENERAL TRADE NOTES.

NOTES AND HINTS ON THE VEGETABLE PRODUCTS OF TROPICAL AFRICA.

J. R. Jackson, *Journ. Soc. of Arts* 1891, 49, 110—111, and 122—123.

Rubber.—The various known kinds of African rubber come from climbing plants of the orders *Apocynaceæ* and *Urticaceæ*, mostly from the former. All plants of these orders should be examined for rubber. Liberian rubber from a tree named "Abba" has a considerable export capable of great development if systematic planting were undertaken.

Attention should be given to juices from any species of *Euphorbia* as they yield milky juices solidifying on exposure to air which may be useful for mixing with rubber and gutta-percha.

Gutta-percha plants of the order *Sapotaceæ* should be examined for the milky juices of their trunks and for the fats and oils which the seeds contain. The "butter-tree" is of this order, the seeds of which yields gutta-shea the product most nearly resembling true gutta-percha. It is at present used in making hard soaps.

Food products.—The cassava (*Manihot utillissima*) is cultivated in West Africa for the sake of its roots, from which tapioca is made. It is worth extended cultivation.

Drugs.—A large field is open in this department and any plants used by the natives for medicinal purposes should be sent to England for experiment or trial. Plants of the order *Rubiaceæ* should be tested for bitter tonic principles, the mallow family for demulcent properties, the *Euphorbiaceæ* for cathartic properties. The ordeal bean of Old Calabar is used in ophthalmic and other cases and might be worth cultivation. The downdaké (*Sarcocephalus Esculentus*) has attracted attention on account of its properties as a tonic and febrifuge. *Strophantus* (or Kombe) has valuable cordial properties. Several species are probably comprised under this name. The fruits and foliæes should not be gathered till they are ripe, as the immature seeds shrivel in drying and lose some of their active principle. *Vanilla*, which has never been cultivated to any great extent in British possessions, would no doubt flourish in Western Africa.

Oils and Fats.—A large number of new oil seeds have come into the English market from the West Coast of Africa during the last few years. The seeds of any unknown plant should be examined for oil, and if found specimens of the plant should be sent home for the determination of their botanical affinities. The following plants, the characters and value of which are at present not completely known, furnish seeds, the oil from which has found its way into the market in larger or smaller quantities: mutugo (from the *Telfaria occidentalis*), maluku, (from the *Polygala varifolia*), meni (from the *Lophira alata*), owala (from the *pentaclethra macrophylla*), and the M'paga nut from a species not yet identified.

Gums.—Any species of acacia may be expected to furnish a soluble gum.

Resins, or semi-fossil gums, commercially known as copal, are found buried at various depths in the neighbourhood of gum-yielding trees, or on the site of extinct forests. Amine found in Zanzibar is the most valuable variety. In hambane copal discovered in 1883 has fetched 80*l.* to 100*l.* a ton. Ogea gum was introduced from the Gold Coast in the same year.

Dyes.—The Yoruba indigo, though used by the natives, has not found its way to England. Downdake, and the yellow dye plant of the Soudan (*Cochlospermum tinctoria*) are worth more attention than they have received.

Fibres.—There is a wide field for the utilisation of fibrous substances. The leaf stalks of the bamboo palm of West Africa seem likely to become important for brush making. The Bolobolo fibre brought to notice in 1889 seems likely to command a considerable price.

Perfumes.—In collecting specimens of fragrant plants for transmission to England for examination, care should be taken to dry the fragrant part of the plant thoroughly.

THE RESULTS OF IMPROVED COKE OVENS.

At the meeting of the Society of German Ironmasters, held on January 31st, in Düsseldorf, Herr F. W. Lürmann, of Osnabürek, read a paper on "Coke Oven Progress, with special regard to obtaining by-products," of which the following is an abstract: For obtaining by-products in coke oven working, which began some 35 years ago, and at first met with little acceptance, the Hoffmann-Otto oven takes first rank, there being at present in Germany 1,205 of these ovens. The installation of a group of 60 ovens costs 300,000 marks (the mark is equivalent to 23·8 cents.), and the necessary condensation apparatus 420,000 marks. Such a group treats in the course of a year from 57,000 to 70,000 tons of coal, with an average result of from 65 per cent. to 77 per cent. of coke, 2·5 per cent. to 4·5 per cent. of tar, and 0·8 to 1·25 per cent. of sulphate of ammonia. The Semet-Solvay oven, the construction of which permits of a stronger formation of the covering masonry, attains a very high temperature, and good coke can be obtained with an addition of from 23 per cent. to 27 per cent. of thin coal. From the same cause the yield is greater than, for example, that of the Coppée oven, which, however, is also a satisfactory oven, 1,000 being in use in Great Britain. For some three years benzine has been obtained direct from the coking-gases; the necessary apparatus, invented by Herr Franz Brunek, is a secret; it costs 5,000 marks per oven. From 3 to 7 kilos. of benzine are obtained from 1 ton of coal. The value of the by-products amounts, for a Hoffmann-Otto oven, irrespective of benzine, to from 3,400 to 5,000 marks, the average being 4,600 marks; for all the ovens of this system in Germany 5,600,000 marks. The old idea that in obtaining by-products the quality of the coke is prejudiced no longer appears to hold good. In the discussion which followed, Herr Hüssener mentioned that a certain water-contents, according to the quality of the coal from 10 per cent. to 17 per cent., is advantageous in coking, and that coal poor in gas are not suitable for obtaining by-products; the limit is about 80 per cent. to 82 per cent. coke-yield in the crucible.—*Engineering and Mining Journal*.

COMMERCIAL, &C., PROGRESS OF RUSSIA.

Taking the mining products of the country, we find first that the production of gold amounted in quantity to 720 cwt., and in value to 5,051,000*l.* in 1881, and in 1889 to 733 cwt. and 5,117,000*l.* The principal centre for this production is Eastern Siberia, where the auriferous sand of the Djalou river has lately increased the amount produced. In 1888 the production of Russian gold represented a proportion of 21·6 per cent. of that of the whole world, 30·7 per cent. falling to the United States, and 25·3 per cent. to Australia. Of platinum, 53 cwt. were produced in 1888, and the working of the metal is concentrated exclusively in the Ural, in the Government of Perm, at the mines of Nijnigul and Govoblagodat. There are two large establishments at St. Petersburg engaged in the purification of the metal. Of silver, 144 cwt. were exported in 1883 and 297 cwt. in 1888. This metal is obtained chiefly from the mines of Altaï and from the mines of the Kirghese steppes.

Lead is only produced in Russia as a secondary product of the treatment of argentiferous ores, and the production of this article falls very much below the requirements of the country, which imported 391,000 cwt. in 1889 and 423,000 cwt. in 1890.

There are 21 copper foundries which treated 2,224,000 cwt. of ore and produced 90,000 cwt. of bar copper in 1888. The principal centres of this production are the Ural and the Caucasus. There are 116 copper mines at present in working. The zinc industry is almost exclusively concentrated in Poland, the number of mines being 12, from which 900,000 cwt. of ore have been extracted. The product of the country has only furnished 74 per cent. of the quantity required for home consumption, the remainder being supplied by importation. Of tin almost the entire quantity comes from abroad. Mercury is worked at one place only, namely, Nikitooke, and 3,200 cwt. of pure mercury were produced in 1888 and 6,000 cwt. in 1890. Russia is now commencing to export mercury.

The iron industry is very important, 522 mines in the Ural supplying 15,750,000 cwt. in 1888, 20 mines in the South, 4,500,000 cwt., 63 mines in Poland, 3,857,000 cwt. The total product exceeds 27,960,000 cwt. The number of establishments producing iron was, according to the latest returns, 132, with 200 blast furnaces, which worked up over 26,357,000 cwt. of ore, and produced about 13,178,000 cwt. of iron, of which three-fourths were obtained by the charcoal blast furnace, and one-fifth by the coke furnace. The Ural holds the first place in the production of iron, and the establishments which show the largest out-turn are those of the Compagnie de la Nouvelle Russie, the Compagnie Huta Bankowa, and the Compagnie de Briansk. In those districts in which the blast furnaces work with charcoal, the metallurgical industries can only increase their production to a limited extent, by reason of the difficulty of obtaining an increased quantity of combustibles; in those in which coal is used (Southern Russia and Poland) the development is much more rapid. In 10 years the total product has increased 50 per cent.; in the provinces of the South and South-west it has quadrupled, and in Poland it has trebled. The proportion which the Russian production bore to the national consumption was established for 1888 in the following ratios: pig iron, 90 per cent.; finished iron, 85 per cent.; and steel, 96 per cent.

During the same year the number of coal mines working was 330, and they produced 5,078,550 tons of coal; of this quantity 2,346,400 tons were supplied by Poland, 1,700,000 tons by the Donetz basin, 257,140 tons by Moscow, and 192,850 tons by the Ural. The principal mines in the kingdom of Poland belong to M. de Krantsa, the Société Franco-Italienne, and the Société de la Nouvelle Russie. It is principally England and Germany which supply Russia with the greater part of the combustibles for which she is obliged to have recourse to foreign countries. In 1890 England supplied 1,354,800 tons, Germany 139,800 tons, and Austria 11,250 tons. The use of Russian coal on the various railways has increased by 50 per cent. during the last 10 years, and the consumption of foreign coal has decreased in the same proportions.

The production of naphtha is almost exclusively confined to the Caucasus in the peninsula of Apelérion and principally in the neighbourhood of Baku. Petroleum is also worked in the Crimea and in the Transcaucasian districts. After the annexation of Baku to Russia this industry was the object of a monopoly which from 1821 to 1872 yielded to the Treasury an annual revenue of about 89,000 roubles. In the Caucasus the production of naphtha amounted to 3,325,130 tons in 1889, and to 3,845,000 tons in 1890. The principal workings are those belonging to the following companies: Nobel, Baku, Caspienne, Caspienne et Mer Noire, Denho et Cohan, Schibakow, &c. The Nobel Company has 50 wells at work, and the factory belonging to the company is the most important one. It contains a refinery for petroleum and benzine, a factory for lubricating oils, and works for sulphuric acid and carbonate of soda. In this establishment, 707,140 tons of naphtha were treated in 1889, and from this quantity 257,140 tons of refined petroleum were obtained. The vessels belonging to this company are said to represent a value of six millions of roubles; its tank waggons, three millions of roubles.

In 1890 the quantity of petroleum, raw and refined, shipped from Baku, amounted to 2,839,520 tons, of which 765,000 tons were for foreign countries. About 74 per cent. of the product goes into the interior, 26 per cent. to foreign countries, principally to England, Turkey, Austria, Germany, Belgium, and Italy.—*Board of Trade Journal*.

THE NEW FRENCH CUSTOMS TARIFF.

The French Tariff Law of the 11th January 1892 has now been printed and issued to the public, and two translations of the law into English have also been published. The first of these is issued by the International Customs Tariffs Bureau, in Brussels, and forms No. 22 of the *International Customs Journal*. The second is issued by the Trade and Treaties Committee, and is attached to their Seventh Report which has been presented to Parliament (C.—6641).

This latter return gives the duties now leviable under the new French general and minimum tariffs of 1892 in a comparative form with those levied under the Conventional Tariff of 1882. It is scarcely necessary to say that the duties generally speaking have in the new tariff been raised all round. This, if any one glances at the comparative statement referred to, is at once evident. But another fact will also, at the same time, strike the most casual observer, this is, that so many articles now specially mentioned in the new tariff did not occur, or were not separately distinguished in the tariff of 1882, as not being at that time of sufficient importance, as articles of commerce to be so distinguished; further, that a large proportion of the articles now, for the first time, separately distinguished, are connected with recent inventions of art or science, or have come into demand in the last decade through being used in some recent invention.

It is now proposed shortly to give in review a list of such articles, together with the amount of import duty allotted to each article, and this may be premised by the statement that the duties on such articles are high in the majority of cases. It may also be here stated that the order of the articles according to the French tariff number has been strictly adhered to, and that the duties affixed are those of the minimum tariff as being those levied on articles of British manufacture. The first of these articles to which reference should be made is margarine, oleomargarine, and all other fatty substances to be used as food (No. 31 of the French tariff), such articles will pay 6s. per cwt., over $\frac{1}{2}$ d. per lb. The next is wood pavement (No. 129), which will pay very close on 8d. per cwt. Pâtes de cellulose (No. 158) wood pulped, will pay, if treated by mechanical pressure, dry, 5d., or if moist, 2½d. per cwt., the same article, if treated chemically, will pay 10d. Amongst builders' materials, tiles, machine-made (No. 181c) will pay 4d. per cwt., and squares of compressed cement (No. 186) will pay duties varying from 5d. to 1s. 8d. per cwt., according to state.

Mineral wax or ozokerite (No. 194) will pay when crude 4s. per cwt., and when refined 16s. Paraffin and vaseline (No. 199) will pay respectively 12s. and 11s. 2d. per cwt. Ether (No. 266a) will also pay 12s. per cwt., and chloroform (No. 266b), 30s. per cwt., collodion (No. 266c) being also taxed 12s. per cwt. Pyrolignite (No. 271a) of lead will pay 1s. 2½d. per cwt., while pyrolignite of lime will pay 9½d. Sulphate and other salts of quinine will pay 30l. per cwt., or 5s. 4d. per lb. Chemical manures, being chemical products to be used in agriculture (No. 281a), are to be imported free. Celluloid in lumps, cakes, or sheets (No. 281b) will pay 1l. 10s. per cwt. Charcoal specially prepared for electric lights (No. 302) will pay 1l. per cwt. Transparent soaps containing alcohol or sugar (No. 311) will pay 16s. per cwt. Dextrin and other products derived from fecula and starches (No. 319b) will pay 5s. 2d. per cwt. Electric incandescent lamps (No. 361), will pay, if with their mountings, 7l., and 14l. per cwt. if without the mountings.

Under tissues of silk there is also a fresh category, tissues of artificial silk of all sorts (No. 459); these, if unmixed with other tissues, will pay duty as chemical products which contain alcohol, while, if mixed with other material, the article will pay the duty on the most highly taxed material of which composed.

Turning to paper, there are also several new categories which attract attention: these are paper hangings (No. 461a) which will pay 4s. per cwt. Paper sulphurised (No. 461b) paying 8s. per cwt. Photographer's paper, albuminised (No. 461c), which will pay 2l. per cwt. when not sensitised, and double that duty when sensitised. Also blacked paper (tracing paper) so called "papier au charbon" will pay 1l. per cwt.

There are new categories under the head of cardboard made from cellulose or wood pulped (No. 465); these articles when moulded, compressed, or hardened will pay 6s. 4½d. per cwt. The same articles when lacquered or covered with a uniform varnish, 20s. per cwt., and when decorated with paintings or incrustations, 4l. per cwt.

Turning to leather we find a new category for imitation leather (*cuir factice*) (No. 477), which will pay 10s. per cwt.—*Ibid.*

NITRATE REVENUE IN CHILI.

The *Chilian Times* for February 3rd says that since Chili came into possession of Tarapacá and the other nitrate-producing territories she had received in duties on nitrate and iodine up to the end of 1889 the enormous sum of 110,127,783 dols., as under:—

1880, 1,336,881 dols.; 1881, 5,829,633; 1882, 8,317,712; 1883, 10,176,336; 1884, 10,855,330; 1885, 10,510,182; 1886, 10,599,419; 1887, 13,098,747; 1888, 17,917,858; 1889, 21,485,685 dols.

If to the above there be added the duties received in 1890 and 1891, we shall have a total not far short of 150 millions.

PAPER-MAKING AND RIVER POLLUTION.

At a meeting of the Joint Rivers Committee dealing with the watershed of the Ribble, Mr. W. Naylor, chief inspector for the watershed, submitted his report for the month, which stated—

During the past month the examination of the river Ribble has been continued, and the western section, extending from the Calder confluence to the estuary, inclusive of the Darwen and its affluents, completed. This area collects the drainage of 200 square miles, and bears a population of 311,500. Visits have been paid to, and entries made concerning 14 paper mills, one paper-staining mill, one chemical works, two dye works, one tar distillery, and numerous cotton factories.

Most of this month's work has been on the Darwen, where the paper trade is largely represented. One instance only was noted where dry solids were thrown into the Darwen from a paper mill, but the solids suspended, and very distinctly visible, in paper mill refuse, are serious. A large quantity of soda still finds its way into the river from paper mills, although it is a fact, known widely outside the paper trade, that it can easily be recovered, and, further, at each of the mills where evaporating plant has been erected, I am informed that it is a source of profit. The evaporation of soda has very important secondary effects in lessening pollution. (a) Soaps formed in the boilers from fatty matters on the raw material are burnt in the incinerator or cremator eventually; and (b) in washing the boiled raw material or half stuff for any soda retained in the interstices of the fibre, an amount of dirt and organic matter is always washed out, which also goes right along to the incinerator and is burnt. The annual consumption of soda ash on the Darwen is 3,300 tons. Evaporating plant is installed at the works having an aggregate consumption of 1,720 tons. Assuming half the remainder is used in the process of boiling, there is a residue of about 800 tons thrown into the river annually. But, granting that the whole of the soda has been eliminated from the paper mill refuse, there remains a thick coloured waste liquor from the washers, beating engines, and paper machines, bearing the dirt from the rags, Surat bagging, &c., according to the nature of the mill. From returns kindly supplied by paper-making firms on the Darwen, it is estimated that in this river alone the consumption of raw material is annually 10,300 tons rags; 12,400 tons straw and esparto; 4,700 tons ropes, Surat bagging, canvas, &c.; 3,000 tons waste paper, peat, &c.; giving a total of 30,400 tons to be washed. There are used in addition about 18,000 tons mechanical wood pulp, 950 tons chemical wood pulp, which, while requiring no washing, will lose some proportion as waste during manipulation. The filthy condition of some of this raw material is worthy of note, too, the albuminoid ammonia, being as high in an average of six representative samples of paper waste as in the average urban sewage, namely, 0.4 parts per 100,000. But the point calling for earliest attention is the quantity of solids in suspension, as these could be lessened to a great extent without plant or apparatus, coupled with maintaining cost, ignoring their importance as polluting agencies. The average suspended solids in white paper mills is 85.1; brown paper mills, 98.1; ditto dissolved solids, white paper mills, 80.1; ditto brown paper mills, 170.9. Quantity of water turned into river by white paper mills, 2½ millions galls. per day; ditto brown paper mills, ½ million galls. per day; total 3 millions galls. daily. A deduction, however, should here be made

for the brown paper mills, as they use, in most instances, river water directly, already contaminated by the white paper mills; but, allowing them the benefit of creating no more pollution than the white paper mills, we get a uniform waste bearing in suspension 85 grains per gallon, and holding in solution 80 grains per gallon, or 5,090 tons per annum of suspended solids, and 4,700 tons per annum of dissolved solids, at six days per week, and this amount, large as it appears (only 20 per cent. of the raw material used), is rather under than over the mark, allowing the river an initial burden of 20 grains per gallon dissolved solids. It was found upon experiment that a mixture of white mill refuse lost 98 per cent. of suspended solids by subsidence only, and a mixture of brown mill refuse lost 85 per cent. by subsidence only. If, therefore, this refuse could be turned into a receptacle allowing a subsidence before entering the river, much good would be done. But such receptacles must admit of absolute quiescence; continuous tanks are useless, as the fibre is extremely light and finely divided. The continuous tanks at Spring Vale paper mill, of 27,000 gallons capacity, brought about a reduction of 2 per cent. only in suspended solids, and the effect at Primrose Lodge, Clitheroe, is about the same, but at both places there is additional treatment. The great desiderata at paper mills are evaporating plant and receptacles in duplicate to hold six hours' refuse at the least, and the sooner steps are taken in this direction the better it will be for the river Darwen. In the discussion of these matters with gentlemen in the paper trade, inspectors are treated with every courtesy, and I am strongly of opinion that, on the whole, they are willing to meet the reasonable demands of this committee. Considerable expense would be incurred in providing plant for evaporation, and it depended entirely on the value of soda ash whether the outlay was remunerative or not. Speaking generally, however, he thought the inspector had received correct information when he said the provision of such plant would remunerate manufacturers in the end. He thought he might say, as far as the paper trade was concerned, they were prepared to carry out any reasonable requirement. In answer to Mr. Smith, the Chairman said the cost of providing the evaporating plant for a moderate-sized mill would be from 1,000*l.* to 3,000*l.*, and he believed the income would pay interest on the capital outlay.—*Chemical Trade Journal.*

DRUG IMPORTS INTO THE UNITED STATES.

The full official statistics of the foreign trade of the United States for 1891 are now to hand. They give the following results, so far as concerns the imports of some of the principal drugs:—

Duty-free.

	1891.	1890.
	Lb.	Lb.
Alizarine	1,123,632	2,667,103
Cinchona	2,861,421	3,274,117
Gum arabic	826,248	935,841
Camphor (crude)	1,982,083	1,400,483
Shellac	7,485,456	5,837,298
Liquorice root	82,539,923	45,360,615
Bleaching powder	108,880,381	105,090,046
Opium	451,129	Dutiable
Potash, chlorate	3,134,461	"
" muriate	78,144,810	63,775,938
Quinine	2,527,099	3,790,297
Sulphur	116,971	131,096
Vanilla	228,435	179,016
Nutmegs	1,382,900	1,289,312
Pepper, all kinds	12,675,906	15,923,819

Dutiable.

Glycerin	1,976,333	7,230,405
Sulp. copper	15,123,134	805,518
Quinine	7,038	11,853
Cream of tartar	25,974	15,759,521

—*Ibid.*

THE PRICE OF PLATINUM.

Platinum has fallen considerably in value lately, and now costs only about one-half of its price in September 1890, when it attained the highest quotation known. The following figures (in marks per kilo.) represent the fluctuations of the metal during the last five years:—

1887	July 1,925	Sept. 1,880
1888	Feb. 1,000	May 970	Aug. 950	Nov. 1,000
1889	Jan. 1,000	March 1,100	Aug. 1,070	Oct. 1,000	Nov. 1,075	Dec. 1,200
1890	Jan. 1,500	June 1,200	Sept. 2,500	Oct. 2,200	Nov. 2,100	..
1891	Jan. 1,750	July 1,550	Sept. 1,400	Oct. 1,500	Dec. 1,275	..
1892	Feb. 1,250	March 1,200

—*Ibid.*

THE SUPPLY OF TUNGSTEN.

The use of tungsten in the manufacture of tungsten steel has created a very considerable demand for wolfram, the principal ore of that metal and the supply being limited its market price has risen to a higher figure than has been obtained for many years. It would appear from recent experiments, of which we have been informed, that the advantages of tungsten steel will prove so important that this alloy will come into quite general use, perhaps taking the place of nickel steel. In view of the high value of tungsten at the present time it is worth the while of prospectors to look for its ores.—*Engineering and Mining Journal.*

ALKALI, &c. WORKS.

A Bill to amend the Alkali, &c. Works Regulation Act, 1881.

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

1. The works specified in the schedule hereto shall be added to those specified in the schedule to the Alkali, &c. Works Regulation Act, 1881, and shall be scheduled works for the purposes of that Act.

Provided that if the process used in any work specified in Part I. of the schedule hereto shall be such that no sulphuretted hydrogen is evolved therein, the work shall not be deemed to be included in the schedule.

2. Works in which salt is produced by refining rock-salt, other than those where the rock-salt is dissolved at the place of deposit, shall not be within the provisions of the Alkali, &c. Works Regulation Act, 1881, in regard to works in which the extraction of salt from brine is carried on, or of any order made or to be made under section ten of that Act.

3. This Act shall come into operation on the first day of April in the year one thousand eight hundred and ninety-three, but certificates of registration may be applied for and issued at any time after the first day of January in that year.

4. This Act may be cited as the Alkali, &c. Works Regulation Act, 1892.

SCHEDULE.

Part I.

(1.) Alkali waste works, that is to say, works for the recovery of sulphur from alkali waste or for utilising the sulphur or any other constituent of such waste.

(2.) Barium works, that is to say, works for the manufacture of barium compounds from barium sulphide.

(3.) Strontium works, that is to say, works for the manufacture of strontium compounds from strontium sulphide.

(4.) Antimony sulphide works, that is to say, works for the manufacture of antimony sulphide.

(5.) Bisulphide of carbon works, that is to say, works for the manufacture of bisulphide of carbon.

Part II.

(6.) Venetian red works, that is to say, works for the manufacture of Venetian red, crocus, or polishing powder by heating sulphate or some other salt of iron.

(7.) Lead deposit works, that is to say, works where the sulphate of lead deposit from sulphuric acid chambers is smelted.

(8.) Arsenic works, that is to say, works for the preparation of arsenious acid, or where nitric acid or a nitrate is used in the manufacture of arsenic acid or an arseniate.

(9.) Nitrate and chloride of iron works, that is to say, works in which nitric acid or a nitrate is used in the manufacture of nitrate or chloride of iron.

(10.) Muriatic acid works, that is to say, works, not being alkali works as defined in the Alkali, &c. Works Regulation Act, 1881, where muriatic acid is made.

(11.) Fibre separation works, that is to say, works where muriatic acid gas is used for the separation of silk or woollen fibre from vegetable fibre.

(12.) Tar works, that is to say, works where gas tar is distilled or is heated in any manufacturing process.

(13.) Zinc works or works in which zinc is extracted from the ore.

BOARD OF TRADE RETURNS.

SUMMARY OF IMPORTS.

	Month ending 31st March	
	1891.	1892.
	£	£
Metals.....	1,831,153	1,850,188
Chemicals and dyestuffs.....	706,735	764,052
Oils.....	534,674	537,820
Raw materials for non-textile industries.	2,591,726	2,593,041
Total value of all imports	35,253,050	36,704,177

SUMMARY OF EXPORTS.

	Month ending 31st March	
	1891.	1892.
	£	£
Metals (other than machinery)	3,780,663	2,842,986
Chemicals and medicines	846,273	839,111
Miscellaneous articles.....	2,954,560	2,616,475
Total value of all exports.....	21,663,378	19,665,382

IMPORTS OF METALS FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Copper:—			£	£

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND
MACHINERY.

APPLICATIONS.

5108. R. Fish and W. Smith. Improvements in apparatus for regulating liquid seals in gas washers and the like. March 15.

5125. F. H. Rowlett. *See Class II.*

5214. A. Desgoffe. Improvements in machinery for manufacturing fuel blocks and other articles from plastic material. March 16.

5238. J. A. Yeadon and W. Adgie. *See Class III.*

5239. J. A. Yeadon and W. Adgie. Improvements in apparatus for revivifying gas, lime (sulphide of calcium), and other analogous materials. March 16.

5281. C. Fery. *See Class XXIII.*

5325. H. H. Lake.—From T. Craney, United States. Improvements in evaporating apparatus. March 17.

5377. S. H. Johnson and C. C. Hutchinson. Improvements in apparatus for mixing liquids with liquids and solids. Complete Specification. March 18.

5538. O. W. Ketchum. Improvements in gas generating furnaces or gas producers. March 21.

5558. P. Lucas. Improvements in and relating to the fireplaces of brewers' pans, salt pans, iron and steel furnaces, and other like furnaces. March 22.

5619. J. A. Fisher. Improvements in the construction of non-conducting coverings to prevent the radiation of heat. Complete Specification. March 22.

5659. R. L. Newman. Improvements in evaporators for the distillation of liquids. March 22.

6134. D. Stewart. An improved vacuum pan. March 30.

6354. T. Thornley. Improvements in kilns or furnaces applicable for the drying and incineration of spent soda solutions. April 1.

6478. F. W. Scott, E. G. Scott, and F. W. Scott, jun. Improvements in evaporating apparatus. April 4.

6535. W. Birch. Improved means and apparatus for separating solid or semi-solid substances from sludge or other fluid or semi-fluid matters. April 5.

6700. C. D. Abel.—From E. Theisen, Germany. Improvements in surface condensing and refrigerating apparatus. April 7.

6898. R. S. Brownlow. Improvements in apparatus for heating feed-water, applicable also for evaporating and for cooling or condensing. April 11.

COMPLETE SPECIFICATIONS ACCEPTED.*

1891.

6887. J. Peake. Kilns for various purposes. March 23.

8177. F. Smith and W. Travis. Apparatus for drawing off liquids. March 23.

8546. J. C. Mewburn.—From The Maschinenfabrik Grevenbroich. *See Class XVI.*

9181. J. Dawson and J. W. Hampson. An improved construction of refrigerator or cooling pan for chemical and other purposes. April 6.

9310. A. J. Boulton.—From A. Kionne and F. Bredel. Setting and heating retorts. April 6.

1892.

1210. B. Zeitschel. Apparatus for rapidly heating liquids. April 6.

2117. C. F. Betting. Assay or chemical balances. March 23.

3013. N. Hunting. Apparatus for distilling water in the presence of air, and for communicating heat thereto, and for supplying water and air thereto and delivering water therefrom. March 23.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

4982. G. Angel. Improvements in the manufacture of peat fuel. March 14.

4991. C. Heath. Improvements in apparatus or means for utilising small or waste coal or other fuel for steam boiler and other fires and furnaces. March 14.

5031. R. E. P. Craven. An improved apparatus for washing smoke and separating carbon and other matters therefrom. March 15.

5125. F. H. Rowlett. Improvements in the construction of "saturators" used in the manufacture of gas, applicable also for dye-vats and other purposes. March 15.

5173. M. Lauchlan. Carbon diamond fire-lighters. March 16.

5198. J. Laycock and S. B. Clapham. Improvements in apparatus for use in the purification of coal-gas. March 16.

5575. T. O. Dixon. Improvements in the manufacture of perforated fuel. March 22.

5620. F. A. Tagliaferro, A. A. Moore, and R. Campion. Improvements in the manufacture of fire-lighters and artificial fuel. March 22.

5698. J. Tattersall. Fire-lighters. March 23.

5755. A. Mortimer. An improved fire-lighter. March 24.

5994. J. Rudd. Improved apparatus and means for increasing the illuminating power of gas. Complete Specification. March 28.

6000. C. Hunt. Improvements in gas-washing apparatus. March 28.

6020. C. Herzog. An improved method of and means for the regulation of the quality of an artificial gas. March 29.

6062. W. Belton, G. E. Davis, and A. R. Davis. Improvements in the purification of coal-gas. March 29.

6362. C. Bougourd de Lamarre. A new process of and apparatus for the manufacture of illuminating gas. Complete Specification. April 1.

6697. J. Morley. The treatment of ingredients and the manufacture of compound block for use as fire-lighters. Complete Specification. April 7.

6733. D. Rylands. An improved means of utilising gas for warming or heating purposes. April 8.

6819. W. D. Scott - Moncreiff. Improvements in or relating to the treatment of fuel. April 9.

6908. H. Collet and M. Merichenski. Improved mixture intended for use in carburetting air or enriching combustible gas. April 11.

6909. H. Collet and M. Merichenski. Improvements in carburettors. April 11.

7079. C. R. Collins. Improvements in gas-making apparatus. Complete Specification. April 12.

7202. J. N. Mörath and F. S. de Straznicki. Improvements in the manufacture of artificial fuel. Complete Specification. April 14.

7243. C. Fink. Improvements in method of and apparatus for purifying smoke and precipitating the products of combustion thereof. Complete Specification. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7092. A. A. Lister. Apparatus for extracting tar and ammonia from gas. March 23.

7648. E. Stauber. Process and appliances for producing peat-coke cakes. March 23.

8479. J. Ruscoe. Apparatus for charging and drawing gas retorts. April 6.

9180. B. H. Thwaite. Methods of storing inflammable spirits or highly volatile hydrocarbons. April 6.

9366. B. Gibbons and W. P. Gibbons. Apparatus for charging inclined gas retorts. April 13.

9398. P. van Gelder. Separating smoke or soot from air or other gases and utilising the air or gases so purified. April 13.

9457. J. H. Parkinson. Apparatus for obtaining or separating oxygen from atmospheric air. April 13.

10,918. J. C. Chandler. Apparatus for washing or scrubbing gas. April 6.

11,416. J. Bromilow. Gas producers. April 13.

1892.

2367. L. Sepulchre. Gas generator for the distillation of mineral oils and the combustion at a distance of a part or the whole of the products of the distillation, applicable to apparatus for lighting and heating. March 23.

3026. J. A. Dubbs. Manufacture of asphaltum. March 23.

3355. E. W. Harding. Apparatus for the manufacture into blocks or moulded forms of carbonaceous matter for use as fuel. March 30.

3959. J. Johnson.—From H. Kennedy. Coke ovens. April 6.

3995. A. J. Boulton.—From The Chicago Heat Storage Co. Manufacture of fuel-gas. April 6.

4032. T. R. Osbourn. Apparatus for quenching coke. April 6.

4033. T. R. Osbourn. Apparatus for the manufacture of coke. April 6.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATIONS.

5238. J. A. Yeadon and W. Adgie. Improvements in apparatus for distilling mineral or other tars, hydrocarbons, or other analogous liquids. March 16.

5539. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in purifying anthracene and anthraquinone. March 21.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9052. W. P. Thompson.—From P. Kuntze. Manufacture of ammonia and tar from nitrogenous organic substances, and apparatus relating thereto. March 23.

1892.

2367. L. Sepulchre. See Class II.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

5112. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture of new colouring matters. March 15.

5540. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in the manufacture of the red basic naphthalene colouring matter which yields azocarmine on sulphonation. March 21.

5761. The Clayton Aniline Co., Limited, J. Hall, and F. Moore. Improvements in the manufacture and preparation of a yellow colouring matter. March 24.

5811. C. D. Abel.—From C. F. Boehringer and Söhne and Co., Germany. Manufacture of derivatives of amidocrotonic acid. March 24.

5815. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the production of fast colours on the fibre for printing and dyeing purposes. March 24.

6252. R. Holliday and Sons, Limited, and L. G. Paul. Improvements in treating nitroso compounds for use in dyeing animal fibres. March 31.

6630. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Improvements in the manufacture of colouring matters. April 6.

7120. W. Marekwald and J. F. Holtz. Manufacture or production of aromatic disulpho-ethylenediamides, aromatic disulphopiperazides, and piperazine. April 13.

7298. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in the manufacture of dyestuffs. April 16.

7337. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of colouring matters and new materials therefor. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8497. S. Pitt.—From L. Cassella and Co. Production of blue dyestuffs. March 30.

8702. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture and production of colouring matters derived from anthraquinone and alizarine blue. March 30.

9943. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Production of blue colouring matter. April 20.

10,619. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture and production of new basic dyestuffs. April 20.

11,298. E. Schweich and E. Bucher. Colouring matter or dye and methods of extracting and utilising the same. April 6.

1892.

960. A. Bang.—From G. A. Dahl. The production of fast yellow mordant dyeing azo-dyestuffs. March 23.

1231. H. H. Lake.—From Wirth and Co., Agents for A. Leonhardt and Co. Manufacture of colouring matters. April 6.

2718. S. Pitt.—From L. Cassella and Co. Production of black dyes suitable for dyeing wool. April 20.

4677. P. Monnet. Manufacture of new colouring matters or dyes. April 20.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

5297. P. Temming. A new fabric suitable as a substitute for cotton waste for cleaning parts of machinery, and process for making the same. Complete Specification. March 17.

5462. E. Knowles. Manufacture of mixed silk and cotton yarn. March 19.

6550. B. J. B. Mills.—From G. Bergier, France. Improvements in the spinning and treatment of silk in the manufacture of various classes of silk thread. Complete Specification. April 5.

7321. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Process for the preservation of textile fabrics and fibres. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

3960. W. H. Hughes. Cleaning, restoring, and bleaching damaged cotton, or other products from cotton seed, sponges, and all textile material. April 13.

10,556. A. M. Clark.—From La Société La Ramen. Process of ungumming and decorticating textile materials. April 13.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

4984. E. Zillesen, sen. An improved process for dyeing piece-goods. March 14.

5197. R. H. Pickles. Improvement in the composition of compounds of aluminium, iron, and chromium, to be used as mordants. March 16.

5204. W. Crippin and B. Burrell. Improvements in the process of dyeing with indigo cotton, and other fibrous materials, in the raw or manufactured, or partly manufactured state. March 16.

5408. G. Jagenburg. Process for dyeing loose cotton, cotton thread, and woven fabrics. March 18.

6162. E. Hermite, E. J. Paterson, and C. F. Cooper. An improvement in the bleaching of textile and pulping materials in vacuo. March 30.

6304. T. Hoyle and Sons, Limited, and W. N. Neild. Improvements in dyeing cotton and other textile fabrics. April 1.

7339. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the production of fast colours on fibres. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

4928. G. Young and W. Crippin. Apparatus for dyeing and bleaching and otherwise treating cotton, wool, silk, and other fibrous materials in the raw and manufactured or partly manufactured state. March 23.

19,113. W. Ward. Colouring cork used in the manufacture of floor coverings, and apparatus used in colouring the same. March 30.

1892.

2939. A. Ophoven. Art or process for colouring pictures or textile fabrics. March 23.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

5127. J. E. Campbell. Improvements in the utilisation of galvanisers' waste pickle and the like, and in apparatus therefor. March 15.

5195. A. G. Haddock. Improvements in the manufacture of carbonate of soda with recovery of sulphur. March 16.

5225. A. Allhusen, G. E. Edgell, and W. Russell. Improvements in the recovery of sulphur from the waste gases from Claus kilns or similar gases, and apparatus therefor. March 16.

5296. C. J. Bayer. Improvements in the treatment of bauxite or similar minerals for the purpose of obtaining alkali-aluminates or alumina hydrate. March 17.

5388. H. C. Bull. An improved method or process of and means for concentrating and purifying sulphuric acid. March 18.

5425. J. C. Ody. Method for making caustic soda (sodium hydrate). Complete Specification. March 19.

6139. J. C. Ody. New method for manufacturing carbonate of soda. March 30.

6288. H. C. Bull. See Class XI.

6931. H. H. Lake.—From J. H. C. Behnke and the chemische Fabrik in Billwarder vorm. Hell and Staamer, Germany. Improvements relating to the production of pure carbonic acid from the products of combustion of furnaces, kilns, and the like, and to apparatus therefor. April 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

5354. J. J. Hood and A. G. Salamon. Manufacture of cyanogen compounds, and the treatment of substances used therein. March 30.

5801. M. Royon. Apparatus to produce sulphuretted hydrogen. March 23.

9332. Comte T. S. de D. Brochocki. Manufacture or production of chlorine compounds for bleaching. April 6.

9575. D. Rylands. Process or arrangements for the manufacture of carbonic acid gas. April 13.

1892.

1032. P. R. de Lambilly. Method or process for the production of alkaline cyanides. April 13.

4527. C. G. Collins. Process for the purification of brine. April 13.

VIII.—GLASS, POTTERY, AND EARthenWARE.

APPLICATIONS.

5249. J. Slater. Improvements in treating vitreous substances for joining the same or for attaching metals thereto. March 17.

5527. O. Imray.—From The Actiengesellschaft für Glasindustrie vormals F. Siemens, Germany. Manufacture of blown hollow glass with metal insertions. March 21.

7024. R. Cresswell. The treatment of ingredients for the manufacture of compounds specially adapted for coating glass for reflective purposes; also in means for increasing the reflective power of glass so treated. April 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7040. W. A. Kerr. See Class IX.

7547. J. Morton. Kilns for burning retorts, pipes, quarries, and other refractory substances. March 23.

7988. T. C. J. Thomas. Manufacture of glass. April 13.

9960. D. Rylands. Furnaces for glass melting and for similar purposes. April 20.

18,281. C. D. d'Enghein, A. D. d'Engchien, and S. D. d'Engchien. Kilns or ovens for firing terra-cotta and other like materials. March 30.

1892.

1974. W. Leuder. Process of marking glass by acids. March 23.

3586. C. Armstrong. Kilns or ovens for burning and glazing sanitary ware and the like. March 30.

4525. H. D. Fitzpatrick. From M. Schreiber and L. Oettinger. Manufacturing glass bricks. April 13.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

5683. T. D. Harries. An improved artificial stone. March 23.

5746. A. T. Morse. An improved distemper for walls, ceilings, and the like. Complete Specification. March 23.

6608. T. Potter. Improvements in the construction of fire-proof floors. April 6.

6745. V. F. L. Smidth. Improvements in the manufacture of hydraulic cement for building purposes. Complete Specification. April 8.

7034. F. H. Willis and R. Astley. An improved form and method of constructing and fixing fire-proof floors. April 12.

7270. R. Huppertsberg. Improvements in the manufacture of artificial bituminous stone. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

5709. O. Clausen. Manufacture of fire-clay and magnesian bricks, and kilns for firing same. April 13.

6532. J. Jackson. Manufacture or production of decorative material, more especially intended for application to walls, ceilings, or like surfaces. March 30.

7040. W. A. Kerr. Composition designed to serve as a substitute for wood, and also applicable for the manufacture of bricks and crucibles, retorts, and other articles of earthenware. April 13.

8567. O. Imray.—From W. Schlening. Manufacture of artificial stone. March 23.

9319. W. P. Thompson.—From J. P. von Balgooy. See Class XIII.

20,743. J. T. Abell. Paving. March 23.

1892.

2957. H. Hartmann. Manufacture of a resistible material, chiefly designed for building purposes. April 13.

3539. H. Brunson and E. W. Gillett. Building or paving blocks. March 30.

4496. J. S. Holiday. Artificial stones. April 13.

4540. G. M. Graham. Building or paving blocks. April 13.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

4997. J. de Coppet. Improvements in the treatment of minerals, mattes, speiss, and other substances containing nickel for the separation of copper, nickel, and cobalt. March 14.

5026. T. H. Mallaband. Improvements in melting furnaces. March 15.

5255. J. G. H. Batchelor and C. T. Batchelor. Improved means for the recovery of tin and iron from tin plate scrap or other waste material from tinned goods. March 17.

5258. R. Henderson. Improvements in machinery or apparatus for separating and concentrating auriferous and argentiferous ores and extracting gold and silver therefrom by amalgamation. March 17.

5560. R. Heaton. A solder for aluminium. March 22.

5651. H. H. Lake.—From H. F. Brown, United States. Improvements in ore-roasting furnaces. March 22.

6038. G. Wegner. Improved solder for joining together aluminium pieces or pieces of aluminium with other metals. Complete Specification. March 29.

6235. W. H. D. Cleminson. Improvements in casting or founding. March 31.

6399. J. C. Bull. Improvements in the treatment or refining of copper and other metals. April 2.

6454. F. Ryland. An improvement or improvements in tinning cast-iron hollow-ware. April 4.

6567. H. R. Lewis and C. Gelstharp. Improvements relating to the treatment of ores and other compounds containing metals and sulphur, and to apparatus therefor. April 5.

6612. T. Twynam. Improvements in the manufacture of iron and steel. April 6.

6704. S. H. Brown. Improvements in a compound for carburising metals. Complete Specification. April 7.

6814. W. D. Parr and E. H. Crapper. An improved process of surface hardening and annealing steel and iron plates. April 9.

6927. A. Gentzsch. Improved process for winning gold without using mercury. April 11.

7027. C. Raleigh. A combination of matter adapted for use in the process of chlorination and means for producing the same. April 12.

7064. C. T. J. Vautin. An improved process for the separation of lead from ores containing galena and blende. April 12.

7067. A. E. Butler, B. F. Butler, and H. M. Butler. Improvements in furnaces for heating and melting metals. April 12.

7069. G. J. Atkins. Improvements in means and apparatus for separating gold, silver, and other metals from their ores. Complete Specification. April 12.

7151. J. F. Duke and F. Bedman. Improvements in separating or recovering tin from tin plate, and apparatus for the purpose. April 13.

7152. J. F. Duke and F. Bedman. Improvements in producing metal or other castings. April 13.

7159. J. B. Chamberlain. An improved alloy. April 13.

7160. J. B. Chamberlain and A. Gutensohn. An improved process for coating metal with a vitrifying material for the removal of scale. April 13.

7302. A. Turner and M. B. Baird. Improvements in the manufacture of iron and steel. April 16.

7332. G. Retterer. Improvements in galvanising iron, and apparatus therefor. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

213. D. Edwards. Apparatus used in the manufacture of tin, terne, and other coated metal plates. April 13.

214. D. Edwards. Apparatus used in the manufacture of tin, terne, and other coated metal plates. April 13.

215. D. Edwards. Apparatus used in the manufacture of tin, terne, and other coated metal plates. April 13.

795. J. E. Bott. Manufacture of ferro-bronze and other alloys. April 20.

6179. W. T. Rickard. Mechanical and chemico-metal-lurgical treatment of copper, the precious, and other metallic ores. March 30.

7625. A. Tropenas. Manufacture of steel, steel castings, or ingot iron, and apparatus and appliances employed therein. April 6.

8122. B. Krantz and H. Zeissler. Decorating metal articles with other metals deposited thereon. April 13.

8137. S. Pearson and J. H. Pratt. Metallic alloys. March 23.

8529. D. C. Bateman. Apparatus for hardening and tempering steel wire. March 23.

10,144. P. H. Bertrand. Method of forming magnetic oxide (Fe_3O_4) upon the surface of wrought or cast iron. April 20.

15,444. T. H. J. Eskuchen and H. A. Haarmann. Burning of pressed blocks of purple ore, and apparatus or kilns therefor. April 20.

1892.

1565. H. H. Lake.—From J. Gould, jun. Coating of metal plates, and apparatus therefor. March 23.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

4949. A. F. Willman. The generation of electricity for electric lighting and other purposes. March 14.

5245. J. Pedder. Improvements in the production of caustic soda and carbonate of soda by electrolysis, and in apparatus therefor. March 17.

5311. J. C. Richardson. Improvements relating to the construction of electrodes for electrolytic purposes. March 17.

5409. G. E. B. Pritchett and T. W. Pritchett. Improvements in secondary batteries. March 18.

5412. J. F. Bennett and F. A. Colley. Improvements in galvanic batteries. March 19.

5546. J. W. Swan. Improvements in or connected with the electrolytic deposition of copper or other metals. March 21.

5645. L. Pyke and E. S. Harris. Improvements in or connected with electric batteries. March 22.

6006. T. Parker and A. E. Robinson. Improvements in the treatment of electro deposits of metals. March 28.

6007. T. Parker and A. E. Robinson. Improvements in or connected with cells for electrolysing chloride solutions. March 28.

6058. W. F. Taylor. Improvements in machinery for the purpose of hardening and tempering metals by electricity. March 29.

6112. H. H. Lake.—From W. Sleicher, jun., and G. A. Mosher, United States. Improvements in and relating to secondary batteries or accumulators. Complete Specification. March 29.

6288. H. C. Bull. Improvements in or connected with the manufacture of alkalis, chlorine, and hydrogen by electrolysis. April 1.

6289. J. C. Graham. Improvements in the deposition of metals by electrolysis, and in apparatus therefor. April 1.

6405. D. Urquhart and J. M. Small. An improvement in secondary voltaic batteries. April 2.

6428. E. Hancock and A. J. Marquand. Improvements in the manufacture of elements for electric or secondary batteries. April 2.

6465. G. E. Heyl. Improvements in electrical secondary or storage batteries. April 4.

6467. E. Hermite and A. Dubose. Manufacture of the alkaline carbonates or bicarbonates by the electrolytic decomposition of alkaline chlorides in the presence of gelatinous alumina or chloride or other salt of aluminium. April 4.

6637. G. E. Heyl. Improvements in electrodes for storage batteries. April 6.

6722. W. W. Donaldson and R. Macrae. Improvements in battery plates or secondary batteries. Complete Specification. April 7.

6949. J. Marx. Improvements in and apparatus for the electrolysis of solutions of salts or compounds of the alkalis, more especially intended for the manufacture or production of alkalis and chlorine and for bleaching. April 11.

7088. A. W. Wetherelt. An improved dry battery. April 13.

7144. G. H. Cutting. Improvements in secondary batteries. April 13.

7170. T. E. Weatherall. An improvement in primary batteries. April 14.

7220. F. B. Stone. An improved primary battery. April 14.

7226. C. H. A. Hoho and E. A. C. Lagrange. Improvements in or relating to the electric treatment of metal or other bodies. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7960. R. D. Sanders. Apparatus for use in the manufacture of metal tube cylinders, or other articles by electro-deposition. April 13.

8126. G. J. Philpott. Compound dynamo-electric generators. March 30.

9079. C. Hoepfner. Electrolytic extraction of metals and the electrolysis of other substances. March 30.

9628. D. G. Fitzgerald. Negative elements (positive electrodes in charging secondary cells) of voltaic batteries. April 13.

9629. D. G. Fitzgerald. Negative elements (positive electrodes in charging secondary cells) of voltaic batteries. April 13.

9689. V. Jeanty. Apparatus for supplying depolarising or other liquids to a series of electric batteries. April 13.

9734. W. Aldred. Dynamo-electric machines. April 20.

9803. W. J. Engledue. Galvanic batteries. April 13.

10,082. P. Jablochkoff. Voltaic batteries. April 20.

10,090. L. Grabau. Process for the electrolytic production of aluminium. April 13.

13,460. The London Metallurgical Company, Limited, and S. O. Cowper-Coles. Coating articles with a new metallic alloy by electro-deposition. April 20.

16,270. W. P. Thompson.—From E. Correns. Accumulators for the storage of electric currents. March 30.

17,655. G. D. Burton, A. H. Eddy, and G. T. Briggs. Heating metals by electricity and machines therefor. March 30.

1892.

2225. G. Nahnsen. Method of purifying electrolytes containing zinc, relating to or connected with the electro-metallurgical production of zinc. April 6.

2329. O. Imray.—From T. J. Montgomery. Process and apparatus for bleaching by electrolysis. March 23.

2913. G. Nahnsen. Electro-metallurgical extraction of zinc. March 23.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

5794. G. H. Ilikins. Improved washing compounds. March 24.

5938. R. Bell and G. H. Barber. Improvements in the manufacture of soap. March 26.

6953. E. J. J. B. Benoit and J. S. y Vila. Improvements in the method of extracting stearine and oleine from tallow, and in apparatus therefor. Complete Specification. April 11.

COMPLETE SPECIFICATION ACCEPTED.

1891.

9431. H. H. Lake.—From La Société Anonyme des Parfums Naturels de Cannes. Purification of fatty substances. March 30.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

5120. H. W. Pieton and S. E. Linder. Improved manufacture of vermilion. March 15.

5287. J. W. H. James. Improvements in the manufacture of white lead, and in apparatus therefor. Complete Specification. Filed March 17. Date applied for October 1, 1891, being date of application in France.

5862. J. R. Carnthers. Improvements in colour cakes, blocks, or sticks for marking or colouring purposes. March 25.

6009. S. Z. de Ferranti and J. H. Noad. Improvements in the production of white lead and chrome pigments. March 28.

6516. G. W. Scollay. Improvements in the manufacture of pigments. Complete Specification. April 5.

6542. J. S. Fairfax.—From F. Crane, United States. Improvements in the manufacture of pyroxyline solutions and compounds for varnishes and coatings. April 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

3832. J. H. Noad. Manufacture of white lead. April 6.

6683. R. J. White. Manufacture of white lead. April 20.

8296. A. MacLean, jun. Transparent coloured materials for decorative purposes. March 23.

9193. R. Jacks.—From G. Sharp. Composition for coating ships' plates and the like. March 30.

9267. W. B. Lawson and H. Schofield. Manufacture of black-lead blocks. April 6.

9319. W. P. Thompson.—From J. P. von Balgooy. Process and compositions for coating walls and similar surfaces to prevent the penetration of damp. March 30.

1892.

2253. C. H. Bigland. Paints or protective coverings for ships' bottoms and other structures. March 23.

3142. H. Taylor. Manufacture of paints and varnishes, and in the treatment of materials in connexion therewith. April 13.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

5689. F. Riegert. A process for waterproofing all kinds of skins and rendering them more durable. Complete Specification. March 23.

5704. J. T. Hardy. An improved method or process of furnishing moroccos, goat skins, and other leathers. March 23.

5828. C. K. Falkenstein and K. K. Falkenstein. An improved method of rapid tanning with the aid of electricity. March 25.

6104. C. W. Luther. The production of a cement or glue for joining wood. March 29.

6416. W. P. Thompson.—From F. A. Wolff, Germany. Improvements in and in apparatus for the treatment of liquid gelatin or glue for the ultimate production of plates or sheets of such. Complete Specification. April 2.

7150. C. J. Sanders. A process for treating the entrails or intestines of animals to render them waterproof and useful for industrial purposes. April 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7106. A. Huillard. Process of decolourising and clarifying tanning liquors or tannic extracts. April 6.

9624. W. Crowther and J. Crowther. Preserving a solution of tannin and keeping it from fermenting or changing into gallic acid. April 13.

10,871. B. Whiteley. Manufacture of mats, rags, and and similar articles from the skins of animals such as sheep and the like. March 30.

18,003. F. J. Bugg. Manufacture of an improved composition leather fabric. March 30.

19,397. I. Goldschmidt. Process of dyeing, tanning, and mordanting leather, teased fabrics, or other porous materials, and apparatus employed therefor. April 6.

1892.

2429. H. E. Howe. Method of rendering leather used for the outer soles of boots and shoes flexible or pliable. March 23.

XV.—AGRICULTURE AND MANURES.

APPLICATION.

5411. F. W. Saubmann. Improvements in the manufacture of superphosphates. March 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

5357. H. H. Lake.—From A. Briart and P. Jacquemin. Method for enriching calcareous phosphates, and for manufacturing superphosphates and various by-products. March 30.

1892.

3029. H. H. Lake.—From The Biolytic Gypse Co. Insecticide and fertiliser. March 23.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

5719. T. Drost. Improvements in and relating to the manufacture of refined sugar from raw sugar. March 23.

6160. R. Brockhoff. Improvements in apparatus for manufacturing sugar. Complete Specification. March 30.

7254. G. E. Delory. Improvements in the treatment of fecula and other amylaceous matters, and in apparatus therefor. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8545. J. C. Mewburn. From The Maschinenfabrik Grevenbroich. Crystallisation of saccharine and other solutions. March 23.

8546. J. C. Mewburn. From The Maschinenfabrik Grevenbroich. Treatment of solutions which have been boiled to the granular state. March 23.

21,370. L. Kern. Production of adhesive substances soluble in water, from the gum exuded from almond, cherry, peach, and other trees. April 6.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

5059. G. Sobotka and A. Kliemetschek. Method of and apparatus for producing clear wort. Complete Specification. March 15.

5227. R. Rozenbaum. A process for the treatment of wine. March 16.

6075. G. Sobotka. Method of and apparatus for separating yeast. Complete Specification. March 29.

6286. W. G. Davidson. Davidson's precipitating and hot blast process for treating and cooling distillers' dreg. April 1.

6531. J. F. Wittemann. An improved process of finishing beer. Complete Specification. April 5.

6555. G. M. Johnson and E. de Cock. Improved method of or means for treating beer for improving its qualities and colour. Complete Specification. April 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9763. W. P. Thompson.—From J. F. Theurer. Process and apparatus for effecting the extraction of hops, with the simultaneous production of a fine extract. April 13.

10,135. P. M. Justice.—From A. W. Billings. Method and means for manufacturing beer and ale.

18,511. A. Umbeck. Brewing. March 23.

1892.

3010. W. P. Thompson.—From C. F. Lawton. Process of manufacturing beer, ale, wine, cider, or the like. March 23.

3011. W. P. Thompson.—From C. F. Lawton. Method and apparatus for manufacturing beer, ale, wine, cider, or the like. March 23.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

4948. H. J. Allison.—From J. Miner, United States. Process of making food compounds. March 14.

5589. S. L. West. Improvements in apparatus for purifying, sterilising, and filtering water, and rendering the same fit for potable purposes. Complete Specification. March 22.

5725. J. Falcimagne. Improvements in or relating to the preservation of meat and fatty matters. Complete Specification. March 23.

6570. G. J. Epstein. Improvements in the manufacture of a substitute for egg. April 5.

6808. G. Tall. The manufacture of an improved substitute for butter. April 8.

6841. W. Crawford. An improvement in the manufacture of malt bread, biscuits, confectionery, and other articles of diet. Complete Specification. April 9.

7043. C. Saville. A new or improved food product, and process of producing the same. Complete Specification. April 12.

B.—Sanitary Chemistry.

5077. D. Harwood. Improved means for preventing the pollution of the atmosphere in large cities and towns. March 15.

6211. J. Price. Improvements in the treatment of sewage. March 31.

6396. F. W. Lacey. Improvements in apparatus for the treatment of noxious gases. April 2.

6731. H. Grimshaw. A new and improved method for the purification of sewage and waste water from manufacturing processes. April 8.

6882. H. C. W. Baldwin. Improvements in the construction and arrangements of purifying and disinfecting apparatus. April 9.

C.—Disinfectants.

5036. J. B. Dewhurst. An improved compound for disinfecting and other purposes. March 15.

5979. F. W. A. Hille. Improvements in disinfectants. March 28.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1891.

7345. R. Riek and O. Dahm. Manufacture of artificial "human milk" and other easily digestible foods. March 23.

1892.

3470. G. F. Redfern.—From G. H. Neuhauss, J. F. H. Gronwald, and E. H. C. Oehlmann. Apparatus for sterilising milk and other fluids. April 20.

C.—Disinfectants.

1891.

8827. R. Armstrong. Manufacture of detergent powder. March 30.

9491. T. H. Williams. Manufacture of disinfecting powder. April 13.

9492. T. H. Williams. Manufacture of disinfecting powder. April 13.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATION.

5981. J. E. Hollidge. A treatment of paper or other material whereby writings become unalterable by the action of time or exposure. March 28.

COMPLETE SPECIFICATION ACCEPTED.

1891.

20,225. C. Kellner. Treatment of short fibres, particularly paper pulp, forming therefrom rovings and other goods. March 23.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

5745. J. Pfeiffer and W. Krauth. An improved process for the production of oxygenated pyrrazol derivatives. March 23.

7269. W. P. Thompson.—From W. C. Tiffany, United States. Improvements in extracts and distillates of ruine, hymenosepalum, torr, and their by-products, and the processes of producing the same. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8584. L. F. Riedel. Manufacture of an iodine derivative of phenacetin. March 23.

9431. H. H. Lake.—From La Société Anonyme des Parfums Naturels de Cannes. See Class XII.

9450. J. Y. Johnson.—From F. von Heyden. Manufacture of iso-eugenol and poly-iso-eugenol. March 30.

9763. W. P. Thompson.—From J. F. Theurer. See Class XVII.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

5597. J. W. McDonough. Improvements in the art of producing coloured photographs. Complete Specification. March 22.

6342. V. Mathieu. Process for producing coloured photographs. Complete Specification. April 1.

6543. J. S. Fairfax.—From F. Crane, United States. Improvements in the manufacture of pyroxyline solutions and compounds for photographic or other films or coatings, and for solid or massive articles. April 5.

COMPLETE SPECIFICATION ACCEPTED.

1891.

7785. B. Krantz and H. Zeissler. Method and apparatus for reproducing photographs. April 13.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

5499. E. Davies. Improvements connected with explosive and non-explosive projectiles, and in an explosive compound to be used with the explosive projectile. March 21.

6258. O. Imray.—From MM. Rotten and Co., Germany. Improved manufacture of explosives. March 31.

6448. C. O. Lundholm and J. Sayers. Improvements in the manufacture of explosives. April 4.

6470. R. H. Courtenay. Improvements in and means for discharging highly explosive substances or fluids for war and mining and other purposes. April 4.

6548. D. Morrison and J. Somerville. Improvements in and relating to matches for lighting purposes. April 5.

7238. J. K. von Falkenstein and A. M. Bohn. New or improved manufacture of smokeless powder and high explosives. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9503. H. T. Ashton. Percussion fuses. April 20.
10,747. J. Selwig and B. Lange. Apparatus for nitrating cotton, cellulose, straw, &c. April 20.
12,474. J. Heath and W. Frost. A safety fuse lighter. April 20.

XXIII.—ANALYTICAL CHEMISTRY.

APPLICATIONS.

5211. E. E. Duller. An improvement in fractional distillation. March 16.
5281. C. Ferý. A new instrument for the measurement of the refractive index of light in liquids. March 17.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 5.—VOL. XI.]

MAY 31, 1892.

[Non-Members 30/- per annum; Members 21/- per Set of extra or back numbers; Single Copies (Members only) 2/6.]

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, K.C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.

COUNCIL FOR YEAR ENDING JULY, 1892.

President: Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.

Vice-Presidents:

Sir Lowthian Bell, Bart., F.R.S.	<i>Ludwig Mond, F.R.S.</i>
Wm. Crowder.	<i>Dr. Hugo Müller, F.R.S.</i>
<i>James Duncan.</i>	<i>B. E. R. Newlands.</i>
<i>Sir John Evans, K.C.B., F.R.S., &c.</i>	<i>J. C. Stevenson, M.P.</i>
David Howard.	<i>A. Norman Tate.</i>
<i>S. H. Johnson.</i>	<i>Sir John Turney.</i>

Ordinary Members of Council:

A. H. Allen.	<i>E. K. Muspratt.</i>
Arthur Boake.	<i>T. L. Patterson.</i>
<i>Jno. Calderwood.</i>	<i>Boverton Redwood.</i>
Dr. Charles Dreyfus.	<i>Jno. Spiller.</i>
H. Grimshaw.	<i>T. W. Stuart.</i>
Prof. R. Meldola, F.R.S.	<i>William Thorp, B.Sc.</i>

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Row, E.

Honorary Foreign Secretary:

Dr. F. Hurter.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

A. H. Allen.	F. Hurter, Ph.D.
L. Archbutt.	C. C. Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Bernays, M.I.C.E.	Ludwig Mond, F.R.S.
H. Brunner.	B. E. R. Newlands.
E. Rider Cook.	John Pattinson.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Sir John Evans, K.C.B., F.R.S., has been nominated to the office of President; and Professor J. Emerson Reynolds, F.R.S., has been nominated Vice-President under Rule 11.

Dr. F. Hurter, Dr. W. H. Perkin, F.R.S., Mr. John Spiller, and Professor T. E. Thorpe, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. Thos. Tyrer has been nominated an Ordinary Member of Council under Rule 17, in the place of Mr. John Spiller, nominated a Vice-President.

Mr. Ludwig Mond, F.R.S., has been nominated Foreign Secretary; and the Treasurer has been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18:—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in London on the 20th, 21st, and 22nd July next. A detailed programme appears in this issue. Books of Coupon Tickets will be provided upon application to the Hon. Local Secretary, and will be wanted as vouchers for visits to works and excursions.

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is prepared to offer 5s. apiece for copies of the Society's Journals for January 1883 in saleable condition.

LIST OF MEMBERS ELECTED, 23rd MAY 1892.

Allen, Walter W., c/o the Pueblo Smelting and Refining Co., Pueblo, Colorado, U.S.A., manager.

Bower, W. Ackroyd, Carnbroe Chemical Works, Coatbridge, N.B., chemical engineer.

Brooke, Wilton, Ashville, Stairfoot, Barnsley, Works, manufacturing chemist.

Clarke, Chas., MacLoutsie, Bechnanaland, South Africa, analyst and assayer.

Dodd, Archelaus, 135, Coleman Street, Whitmoreeans, Wolverhampton, electro chemist.

Gilmonr, Jas. D., 138, Aitkenhead Road, Glasgow, chemist.

Hamilton, Robt., Leeds Steel Works, Limited, Leeds, analytical chemist.

Moore, Dr. G. Dunning, 25, Catharine Street, Worcester, Mass., U.S.A., professor of chemistry.

Paine, Angustus G., The New York and Pennsylvania Company, Times Building, New York City, U.S.A., paper manufacturer.

Pope, Wm. J., 43, Hartismere Road, Walham Green, S.W., chemist.

Seutter, Dr. Erhard von, Via Treere 4, Görz, Austria, works manager.

Smithson, Saml., Ravensthorpe, near Dewsbury, Yorks, dyer and drysalter.

Taylor, Ernest H., Teinturie "Le Phœnix," Borgerhout, Antwerp, chemist.

Thorp, G. H., Clowes Villa, Lower Broughton, Manchester, engineer.

Wing, Jno. D., Box 59, New York City, U.S.A., merchant.

CHANGES OF ADDRESS.

Archbold, Dr. G., 10 Washington; 121—123, Front Street, New York City, U.S.A.

Barrett, A. A., 10 Liverpool; Isola Perroni, Piazza del Collegio Militare, Messina, Sicily.

Barrow, Jos., 10 Failsforth; 65, Bromboro' Road, Lower Bebington, Birkenhead.

Bartlett, F. C., Journals to c/o American Zinc Lead Co., Cañon City, Colorado, U.S.A.

Beckett, G. H., 10 London; c/o Alfred Nobel, San Remo, Italy.

Benjamin, Dr. M., 10 West 121st Street; 77, West 50th Street, New York City, U.S.A.

Berenger, J. J., 10 Treon Road; Basset Road, Camborne, Cornwall.

Boothby, Chas., 10 Westminster; The Hollies, Mile End, Stockport.

Cargey, W. E., 10 Newcastle; dalla Signora Poccardi, 51, Via alla Ponte Mosca, Torino, Italy.

Colwell, W. E., 10 London; c/o B. P. Clapp Ammonia Co., Cincinnati, Ohio, U.S.A.

Conroy, Jas. T., 10 Montpellier Crescent; Hunstanton, Hamilton Road, New Brighton, Cheshire.

Crichton, D. G., 10 Broken Hill; Nundle, viâ Tamworth, New South Wales. (Journals.)

Davis, Chas., 10 Oakfield Road; 3, Leitrim Terrace, High Street, East Ham, E.

Fleck, Hermann, 10 Philadelphia; F'hland Strasse 14, Tübingen, Germany.

Fletcher, R. J., 10 London; 50, Maitland Street, Halifax, Nova Scotia.

Gowland, Wm., 10 London; Buena Vista, Frodsham, Cheshire.

Gray, John, 10 Johnstone; Pentland Oilworks, Loanhead, N.B.

Gregory, Wm., 10 Ashford; Steam Brewery, Dartford, Kent.

Haller, G., Journals to 86a, Leadenhall Street, E.C.

Hamilton, Oswald, 10 London; c/o The Northfleet White Lead Co., Northfleet, Kent.

Heron, John, 10 Worple Road; Ellerdale, Cottenham Park, Wimbledon.

Holloman, F. R., 1/o Rawcliffe Bridge; 3, Laxton Terrace, Sedgwick Road, Leyton, E.

Johnstone, L., 1/o Newcastle; 1, Leadenhall Street, E.C.

Longshaw, Jas., 1/o Manchester; 3, Church Road, Seaforth, near Liverpool.

Lowe, Jas. S., Journals to c/o Oriental Bank Estates Co., Ltd., Port Louis, Mauritius.

Lowman, Dr. Oscar, 1/o Jefferson Avenue; 424, Brush Street, Detroit, Mich., U.S.A.

Mallalieu, T. C., 1/o Manchester; Anlage 24 C., Heidelberg, Baden.

Mond, L., Journals to 20, Avenue Road, Regent's Park, N.W.

Moult, John, 1/o Gladstone Terrace; Underhill, Low Fell, Gateshead.

Panton, J. A., 1/o Abbots Langley; 7, Penbridge Villas, Bayswater, W.

Preston, E. S., Journals to 30, Percy Street, Liverpool.

Richardson, C. T., Journals to 3A, Portman Mansions, Baker Street, W.

Riddell, Robt., 1/o Leicester; c/o S. Allsopp and Sons, Limited, The Brewery, Barton-on-Trent.

Scott, Ernest, 1/o Hampstead; 67, Lord Street, Liverpool.

Sendder, F., 1/o Clapham Common; 146, Earl's Court Road, South Kensington, S.W.

Sewell, Parker, 1/o Alice Street; 194, South Eldon Street, South Shields.

Smith, A. J., 1/o Fir Vale; 103, Rock Street, Pitsmoor, Sheffield.

Weldon, Ernest, 1/o Noel Street; 300, Radford Road, New Basford, Nottingham.

Westmoreland, J. W., 1/o Leeds; 2, City Road, Finsbury Square, E.C.

White, H., 1/o Rotherham; 80, London Road, Carlisle.

Wigg, G. L., 1/o Runcorn; Brow Head, Windermere.

Williams, R. Greville, 1/o Heywood; Greenfield House, Hopwood, near Manchester.

Williamson, Robt., 1/o Middlesbrough; c/o Jos. Williamson, Camp Terrace, North Shields.

Wilson, J. Millar, 1/o Ridley Park; Eddystone, Delaware Co., Pa., U.S.A.

CHANGES OF ADDRESS REQUIRED.

Graham, J. A., 1/o Dunmow, Essex.

Leeming, T. H., 1/o Burneston House, Plaistow, E.

Lees, Asa, 1/o 76, Duncombe Road, Upper Holloway, N.

Milne, G. A., 1/o Norton, Malton, Yorks.

Reay, T. B., 1/o Herrington Street, Sunderland.

Whelan, E. J., 1/o Star Chemical Co., Wandsworth Bridge Road, Fulham, S.W.

MEMBER OMITTED FROM JANUARY LIST.

Lee, J. W. Richmond; 70, St. Helen's Gardens, North Kensington, W.

Deaths.

Hofmann, Prof. A. W., F.R.S., 10, Doratheen Strasse, Berlin.

Shaw, D., Clayton, near Manchester.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: T. Tyrer.

Vice-Chairman: W. Crowder.

Committee:

C. F. Cross.	W. Ramsay.
J. Dewar.	B. Redwood.
A. G. Green.	W. S. Squire.
S. Hall.	G. N. Stoker.
C. W. Heaton.	F. Nanier Sutton.
D. Howard.	Wm. Thorp.
W. Kellner.	T. E. Thorpe.

Hon. Local Secretary: John Heron,
Ellerdale, Cottenham Park, Wimbledon.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman:* Wm. Thorp. *Secretary:* John Heron. *Committee:* C. C. Hutchinson, B. E. R. Newlands, F. G. Adair Roberts, A. Gordon Salmon, T. Tyrer, and Frank Wilson.

SESSION 1891-92.

1892:—

May 30th:—

Dr. C. R. Alder Wright, F.R.S. "On some Aluminium Alloys."

Mr. J. A. Nettleton. "Vinegar."

June 13th:—

Professor V. B. Lewes. "Oil Gas."

Mr. Watson Smith. "The soluble Bituminous Constituents of certain Japanese Coals."—*cont.*

Meeting held Monday, 2nd May 1892.

MR. THOS. TYRER IN THE CHAIR.

ON THE DESTRUCTIVE DISTILLATION OF WOOD.

BY JOHN C. CHORLEY AND WILLIAM RAMSAY, PH.D., F.R.S.

THE destructive distillation of wood has been the subject of numerous researches. Some investigators have carried out experiments on a large scale, using different kinds of wood, and in a rough way, different temperatures; others have investigated more particularly the nature of the distillate and the composition of the gases evolved.

It may not be out of place here to give a brief summary of the previous investigations on the subject, before proceeding to describe our own experiments in detail; but we shall confine our remarks to those woods generally used in practice, viz.: oak, beech, and alder, as it is with these that our experiments have been carried out.

E. Fischer (Dingl. Polyt. J. **238**, 55) gives the results of experiments on beech on the manufacturing scale. Beech yielded, per cent.:—

Vinegar...45, equivalent to 4 per cent. $C_2H_4O_2$ and 1.1 per cent. CH_3O .

Charcoal...23

Gas.....28 (CO_2 , 20; CO , 7; CH_4 , 0.5; H , 0.05).

M. Senff (Ber. **18**, 60) distilled in an iron retort from four to six kilos. of wood; slow distillation (a) was achieved by packing the retort with air-dried wood and heating by means of a small fire; quick distillation (b) by heating the retort to bright redness, introducing the wood into the red-hot retort, closing, and continuing the process

at as high a temperature as possible. He experimented with a number of woods, but to quote his results for oak will serve our purpose.

	Total Distillate.	Tar.	Vinegar.	$C_2H_4O_2$	Charcoal.	Gas.
(a.)	18.15	3.7	41.48	1.03	34.68	17.17
(b.)	15.31	3.2	42.04	3.11	27.73	27.03

His conclusions are that quick distillation causes the formation of more gas, with less distillate and less carbon; that the vinegar is poorer in acid, and that the charcoal is more hygroscopic. He remarks incidentally that the yield of methyl alcohol follows that of acetic acid, being high or low, according as the yield of acid is high or low.

Similar experiments are recorded by C. A. Fawsitt (this Journal, 4, 319). He gives as the most suitable temperature, 350—400°; and for oak his numbers are:—

Vinegar, 47.6 per cent. containing 5.4 per cent. $C_2H_4O_2$; and charcoal, 24.9 per cent.

Lastly, W. Rudners (Dingl. Polyt. J. 264, 88 and 128) distilled small amounts of wood (20—47 grains) in the state of sawdust from glass retorts, using a bath of Wood's alloy as a source of heat. The temperature was made to rise slowly from 150° to 300°, and above. Oak yielded 7.92 and 8.21 per cent. $C_2H_4O_2$, and birch, 9.52 per cent. Comparisons are also given of the yield from other woods, and from cellulose prepared from birch.

A comparative table of yields is also quoted in "Chemistry as applied to Arts and Manufactures" (Mackenzie), but without particulars as to temperature.

The main products of the distillation of wood are water, acetic acid, methyl alcohol, aromatic oils, and charcoal. But the following subsidiary products have been detected:—formic, propionic, butyric, crotonic, iso-crotonic, and angelic acids (Grodski and Krämer, Ber. 11, 1356); acetone, methyl acetate, allyl alcohol, mestyl oxide, phorone (*ibid.*, 7, 1492); aldehyde, methyl formate (C. F. Mabery, Amer. Chem. J. 5, 256); methyl ethyl ketone, and two bodies of the formula $C_8H_{12}O$ and $C_{10}H_{16}O$, supposed to result from the mutual action of acetone on aldehyde, and of acetone on ethyl methyl ketone, and yielding on further dehydration

xylene and lymene; methylal (Fawsitt, *loc. cit.*); and at a low temperature, furfural (Heill, Ber. 10, 936). The tar contains guaiacol and creosol, together with numerous allied bodies; and the pitch, retene in considerable amount.

Analyses of the gas evolved at different stages of the distillation are also given by Fischer (*loc. cit.*). It consists mainly of carbon dioxide (55.6 to 64.7) and monoxide (30.1 to 35.1) together with methane (first three hours, 3.94; 8th hour, 4.67; 11th hour, 5.12; 12th hour, 2.43); traces of ethylene (0.05 to 0.69) and from 1.2 to 4 per cent. of hydrogen.

There appeared to be still room for a careful investigation of the operation of wood-distillation, regard being paid to temperature of the air-bath used to heat the still; to the temperature of the contents of the still; to the yield of acid and wood-spirit at different stages of the distillation; and to the composition of the gas evolved. Much still remains to be done; but the experiments carried out form a contribution to our knowledge of the whole subject.

Description of Apparatus.

The distillations were conducted in glass; the temperature of the still was raised by means of an air-bath with triple walls, an admirable device for securing constant known temperatures; such air-baths are made by L. Buhler, of Tübingen, from a design by Prof. Lothar Meyer. The products of distillation passed through a Liebig's condenser into a receiver; the gases escaping were washed with strong sulphuric acid, for the purpose of retaining methyl alcohol, the vapour pressure of which is so considerable at ordinary temperatures (54.2 mm. at 10°) as to cause considerable loss, provided no means had been taken to arrest its progress. Assuming the escaping gas to have been saturated with methyl alcohol at 15°, the amount retained by 4.5 litres of gas—an average yield—would have been 0.45 gram. It is not certain that no alcohol passed the scrubber of sulphuric acid, but the loss of wood-spirit must have thus been greatly lessened. After passing the scrubber the gases were made to bubble through two large sets of Liebig's bulbs full of potash, to retain carbon dioxide; they then entered a gas-holder of glass, roughly graduated, so that their volume was measured.

The accompanying woodcut shows the arrangement of the apparatus:—

a1 a2. Thermometers.
b. Flask containing the wood.
c. Condenser.

d. Receiver.
e. Sulphuric acid washer.
f1 f2. Potash bulbs.

g. Gauge.
h. Gas-holder.
k. Pipe to water-pump.

To ensure at least partial absence of air in the gases, the still and appurtenances were exhausted by a good water-pump before commencing distillation. The vacuum produced was about 740 mm. at an atmospheric pressure of 760 mm., hence the amount of air remaining in the whole apparatus and ultimately reaching the gas-holder did not exceed as a rule 100 cubic centimetres. To have made a perfect vacuum would have scarcely been possible, because it was necessary to employ an ordinary cork for the distilling-flask, owing to the high temperature of the issuing vapours.

The temperature of the air-bath and the temperature of the wood were read frequently during each distillation. They are illustrated by curves. Thermometers containing nitrogen were employed; in some cases, however, the temperature was too high to be thus registered, and the readings are therefore omitted.

The wood (oak, beech, or alder) was cut into small chips and placed in the flask, a thermometer being inserted so that its bulb occupied the centre of the space, and served to show the progress of the distillation. The temperature of the

bath was then raised, the whole apparatus having been rendered vacuum. As soon as the gas from the still raised the internal pressure, the entrance to the gas-holder was opened, and the gas passed. Distillation was continued until gas ceased to be evolved. But this must be taken only as a general description of the method of conducting experiments, for in many cases it was altered more or less in order to obtain special information.

After the distillation was over the weights of the charcoal, the distillate, and the carbon dioxide bulbs were ascertained, and the total volume of the gas was read. The distillate was re-distilled, and the insoluble oils were weighed. The second distillate, containing chiefly acetic acid and methyl alcohol, was titrated for total acid; and the methyl alcohol was distilled off, after neutralisation of the acid. It was united with the distillate from the sulphuric acid scrubber, diluted with much water. The total carbon dioxide, produced by oxidising the methyl alcohol, &c. with chromic acid was ascertained, and it was assumed for the sake of comparison to be all due to methyl alcohol. This is obviously an incorrect assumption, for the distillate is known to contain a considerable percentage of acetone, which also yields carbon dioxide as one of its oxidation products, besides other substances in smaller amount, many of which would also be oxidised to carbon dioxide; the total amount, however, of all these products was so small that it was thought better to submit them as a whole to some such rough test, rather than attempt a separation which would

have been difficult, and which would in all probability have involved considerable loss.

To gain an idea of the possibility of thus estimating methyl alcohol the following experiments were performed:—

Pure methyl alcohol in about 7 per cent. solution was boiled with a solution of chromic anhydride, and the carbon dioxide evolved was led through a second flask containing a boiling solution of the same oxidising agent. The vapours escaping were caused to return to the second flask by means of an inverted condenser. To the open end of the condenser was attached a flask containing a known volume of a solution of barium hydroxide, $\frac{1}{25}$ normal. The resulting barium carbonate was removed by filtration, and the residual alkalinity determined by titration.

Two experiments conducted on pure methyl alcohol gave 94.8 and 95.6 per cent.; but in estimating the amount of methyl alcohol in the crude products of distillation, no correction was introduced for the deficiency, for the method was regarded as merely a comparative one. The yield of methyl alcohol in the distillate from wood must therefore be understood to be calculated on the basis of CO_2 obtained when it was treated in the manner described above.

It will be best to exhibit the general results in a tabular form first, showing the results at high and at low temperatures. The methods of securing these temperatures will be afterwards described, together with the thermal changes which occur in the woods during distillation.

TABLE I.

Oak.	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.	No. 7.	No. 8.
Weight of wood taken in grams.....	158.0	160.0	160.0	160.0	181.5	181.0	180.0	167.0
Per cent. of charcoal.....	32.9	30.0	29.69	31.25	30.58	33.7	25.00	24.55
Per cent. of distillate.....	55.7	58.1	60.56	58.75	59.87	56.35	59.44	58.09
Per cent. of CO_2 absorbed.....	6.43	3.93*	6.75	7.50	6.50	6.40	8.05	9.58
Per cent. of gas to make up 100 by difference.....	4.97	8.05	3.00	2.50	3.05	3.49	7.51	7.18
Volume of gas after absorbing the CO_2	4,910	6,000	4,350	4,650	4,300	4,000	7,500	7,502
CO.....	61.35	76.2	83.03	81.79	91.82	92.25	71.01	70.77
O.....	5.5	1.5	2.91	1.72
Per cent. by volume of the above gas	C ₂ H ₆	17.44	1.11
CH ₄	29.15	22.3	6.67	2.61	1.73	2.96	11.90	11.90
N by difference.....	13.39	13.88	6.25	1.89	11.55	13.32
Per cent. of pitch from distillate on the wood.....	7.72	8.12	7.93	8.12	8.00	7.60	10.00	9.58
Per cent. of acetic acid distillate on the wood.....	5.6	5.95	5.58	5.58	5.58	5.58	5.76	6.13
Per cent. of methyl alcohol on the wood.....	2.02	1.5	1.78	1.4	1.22	1.32	0.86	1.36
Maximum temperature about.....	345°	369°	356.5°	334	345°	341°	500°	500°

* CO_2 not all absorbed by the bulbs.

Confining our attention first to Table I., in which the results with oak-wood are stated, the chief feature to be noticed is that the percentage of charcoal obtained with a maximum temperature of 334° — 360° varies from 29.69 to 33.7 per cent. The air-bath in these experiments was slowly raised till distillation commenced; and the whole distillation from beginning to end took from 2 to 3 hours. For high temperatures the air-bath was on one occasion raised to the highest temperature obtainable with the burner we possessed, and when the temperature had attained its maximum, the distilling flask was introduced. This made no appreciable difference. The whole distillation in No. 7 lasted only three-quarters of an hour; and in No. 8 about the same time. The table shows the effect of

such rapid distillation very clearly. The charcoal, instead of amounting to 31 per cent. of the wood, drops to 25 per cent. The total weight of distillate is not greatly changed; but the carbon dioxide has increased, and the total amount of gas is more than doubled.* Analysis of the gas shows that a considerable amount of methane has been formed chiefly, apparently at the expense of the water, and perhaps to some extent of the methyl alcohol, for the acetic acid shows a yield a little above the average. It may be conjectured that the carbon and water react giving carbon dioxide and

* It is curious to note that Priestley in 1772 records the observation that a much larger amount of inflammable gas is liberated from wood by rapid distillation.

methane for the most part. It must be remembered that the water of the distillate is not all due to mechanical retention in the wood, which was in all cases seasoned and air-dried; but that we have here the action of nascent carbon on water, partly present as such, partly in course of formation. It is easy to construct an equation which shall represent such an action, it is—

It is true that such an action does not take place between ordinary charcoal and water-gas; but it presents a certain analogy to the action of carbon disulphide on hydrogen sulphide, in presence of copper, when nascent carbon is liberated from the disulphide. We notice also the production of a small quantity of olefines, due, no doubt, to the decomposition of the methane, for some carbon was deposited on the walls of the flask.

Maximum temperature.....	380°	330°	about 500° slow.	about 500° fast.

An analysis of gas produced during distillation of oak on the manufacturing scale by the late Professor Dittmar, kindly furnished to us by Messrs. Turnbull, of Camlachie, gave the numbers:—

CO₂..... 53.3 per cent. of total gas.

The residue consisted of:—

CO..... 82.15
 CH₄..... 13.83
 C₂H₄..... 9.75
 N..... 3.25

The total weight of gas per 100 parts of wood on the large scale amounted to 16 to 18. It will be noticed that the total percentage at 500° found by us was 15 to 16 per cent.; but at lower temperatures 9 to 10 per cent. The percentage of pitch also increases at high temperatures from 8 to about 10 per cent. This probably arises from the formation of acetylene groupings between carbon and hydrogen, and the condensation to aromatic products, the chief of which are known to be creosol and guaiacol. The formation of such aromatic compounds which contain methyl groups does not appear to influence the percentage of methyl alcohol to any great extent.

If we survey the results of distilling beech-wood the same general features appear; but contrasting columns 1 and 2 with 4 and 5, it is to be noticed that the percentage of charcoal falls from 33—34 per cent. to 26—28 per cent., with rise of maximum temperature from 350°—380° to 500°.

There is again a rise, although a smaller one, in the percentage of carbon dioxide, and again an increase in the total gas. Ethylene and marsh-gas again appear, the former in quantity; and the yield of tar is increased. Yet the yield of acetic acid and of methyl alcohol do not appear to suffer. And Table III. giving the results of distilling alder-wood shows the same general features.

Maximum temperature.....	367°	343°	500°	509°

Comparing next the three woods with each other, it is to be remarked (see Table IV., where typical cases are selected for high and for low temperatures) that the total yield of charcoal, both at high and low temperatures, the total distillate and the total carbon dioxide do not appreciably differ for the different woods. The composition and amount of the other gases are also fairly comparable. But alder gives a higher yield of tar than the other woods, and, although the acetic acid is nearly the same for all, the percentage yield of methyl alcohol differs enormously. It is least with oak, very much increased with beech, and greatly higher with alder. In fact about five times as much methyl alcohol (or to be guarded, light spirit yielding CO₂ on oxidation) is produced from alder as from oak. And here also we can see that the influence of a high temperature is not to decrease the yield of methyl alcohol. Attention will be drawn to this fact later.

We come next to consider the temperature of the wood during distillation. It will be remembered that a thermometer was placed so that its bulb occupied the centre of the still containing the wood; hence the temperature of the wood could be compared directly with that of the air-bath.

It is not too much to say that the results obtained are very remarkable. The conclusion may be shortly stated. The change of wood into products of distillation is an exothermic change; wood is of the nature of an explosive. The diagrams of temperature-curves inserted in this paper will amply prove this statement.

Of these three have been selected, which are fair average samples. The ordinates are time in minutes the abscissae temperatures of the thermometers outside and inside the still. While the temperature outside shows a gradual rise, fast at first, and slow afterwards, when the radiation from the air-bath begins to affect the rate of rise of temperature due to the source of heat, and gradually becoming horizontal, when radiation and supply of heat balance, the opposite is noticeable with the inside temperature-curve. There the form of the curve shows that as soon as water has distilled

over, the reaction is exothermic, and as temperature rises, the evolution of heat is more and more marked. Indeed, in all cases it will be noticed that the temperature inside rises considerably higher than the outside temperature; with oak, 30°, with beech, 55°, and with alder 40°.

It is now possible to suggest a reason for the constancy of the yield of acetic acid and methyl alcohol, even when the temperature of the still is greatly raised. It is because the *acetic acid and alcohol are the products of the exothermic reaction*. A supply of heat from without is necessary to start the reaction, as it is in setting fire to gunpowder; the exothermal change continues the distillation independently of any external source of heat.

And yet when we contrast cellulose with acetic acid, methyl alcohol, carbon monoxide, dioxide, and water, we cannot be surprised, for these are among the compounds formed with the greatest evolution of heat from their elements. And it is indeed to be expected that such bodies should be formed from cellulose with considerable evolution of heat.

Next, as regards the progress of the distillations.

Oak.—No. 1. The inside temperature was not determined. Fifty cubic centimetres of distillate were collected before any considerable amount of gas was evolved. There was then a sudden rush of gas, and in 25 minutes the distillation was over.

No. 2. After 45 minutes the inside temperature had risen to 100°, the outside temperature being 275°; about 30 cubic centimetres of distillate had come over, and about 1

litre of gas was collected. Thirty-five minutes later gas was coming off quickly, and the inside temperature had risen to 310°. The outside temperature was kept constant. The inside temperature quickly rose to 360°, and then fell to the temperature of the air-bath.

No. 3. This experiment was conducted as before. The air-bath was slowly heated up. When it had a temperature of 254°, the inside temperature was 90°, and 30 cc. of distillate were collected. Ten minutes later the outside temperature was 270°, the inside temperature 143°, and 40 cc. of liquid had condensed. Gas came off suddenly as before.

No. 4. Both temperatures slowly rose. After 90 minutes the outside temperature was 271°, the inside temperature 261°, and 40 cc. distillate had condensed. Gas then came off quickly. In 20 minutes other 10 cc. had condensed, the outside temperature was 308°, and the inside temperature 299°, while 2 litres of gas were collected. Within the next 15 minutes, the amount of gas had risen to 4 litres, but little more distillate was formed.

No. 5. In this experiment the air-bath was heated up to 315° before introducing the flask, but this does not appear to have affected the results.

No. 6. The temperature of the air-bath was kept as low as possible. The results are shown in the curve, and it is evident that this accounts for the high percentage of charcoal and low percentage of distillate.

No. 7. The air-bath was at 500°; the flask was introduced and its temperature rapidly rose to 115°, when the thermometer had to be removed. No. 8 was treated in the same way.

Beech.—No. 1. The distillation occupied two hours. After 1½ hours the external temperature was 318°, the internal temperature 250°; and a little over two litres of gas had been evolved. In five minutes more the inside temperature had risen to 318°, and three litres of gas were collected. Five minutes later the outside temperature was still only 320·5°, but the inside temperature had reached 368°, and over four litres of gas had passed, and after other five minutes, the gas had reached five litres, but was stopping; the outside temperature was 325°, but the inside temperature had risen to 380·5°. The rise of temperature due to the exothermic decomposition of the wood accounts for the slight rise of external temperature. The temperature of both bath and bulk sank, till the distillation had stopped with outside temperature 315° and inside temperature 332°, and rapidly falling.

No. 2. Practically a repetition of the same phenomena.

Nos. 3 and 4 were distilled at about 500°, or somewhat over, with the same result as with oak.

Alder.—No. 1. The same general behaviour as oak and beech at low temperatures. After one hour the outside temperature was 326°, the inside temperature 250°. Ten minutes later the outside temperature was still 326°, but the inside temperature had risen to 350°. The rise continued, the highest temperature attained being 367°.

No. 2 showed nearly the same results, and Nos. 3 and 4 the same as the beech and oak at high temperatures.

Special experiments were made with beech and with oak in order to ascertain the rate at which acetic acid and methyl alcohol were evolved. The temperature of the air-bath was raised very slowly, and the distillate collected in 10 fractions. The outside temperatures and the percentages of methyl alcohol, calculated on the original weight of wood, are given in the following table:—

	Per Cent. MeOH.
No. 1. Below 135°	0·07
No. 2. 135°—165°	0·07
No. 3. 165°—215°	0·22
No. 4. 215°—275°	0·57
No. 5. 275°—285°	0·60
No. 6. 285°—295°	0·57
No. 7. 295°—305°	0·55
No. 8. 305°—320°	0·41
No. 9. 320°—325°	0·33
No. 10. 325° and above	0·18

The total amounts to 3·57 per cent., but the exposure of the distillates doubtless caused loss. The numbers may be taken as comparative, and it would appear that the alcohol comes over chiefly above 165°, and continues to be formed up to 325°.

Experiments with oak to ascertain the rate of yield of acetic acid at different temperatures were made with 183 grms. of oak. The gases were neglected, and the temperature was raised slowly as in the experiments Nos. 1 to 6 of Table I. The distillates were re-distilled when necessary, and were titrated with sodium hydroxide solution. The following table reproduces the results:—

No.	—	Yield.	Containing Acetic Acid.
1	Up to 120°	cc.	Grms.
2	120°—180°	10	0·1756
3	180°—240°	10	0·7320
4	240°—290°	10	1·0218
5	290°—300°	10	1·4610
6	300°—310°	10	1·5372
7	310°—322°	10	1·0980
8	322°—350°	15	2·3424
9	350°—450°	About 10	1·6104
Total			9·9844

Equal to 5·44 per cent. of acetic acid. There was doubtless some loss on re-distilling; but the results may be taken as comparative, and they show that the acetic acid rises in amount up to 350°, and then falls slightly. Comparing these results with those for methyl alcohol, it would seem that the alcohol is the first product of decomposition, when the exothermic reaction sets in, and that the acetic group is next separated from the wood. The chief evolution of heat appears to be due to the last separation. But it must be noted that the initial form of the temperature curve may be due not perhaps entirely to the commencement of an exothermic reaction, but possibly to some extent to the better conducting power of the dried and partially charred wood. As we do not know the relative conductivities for heat of wet and dry wood, we are of course unable to apportion the relative amounts. Still it is well to bear this in mind. If this be neglected, it would appear that the evolution of methyl alcohol is itself accompanied by evolution of heat, and that the formation of acetic acid causes a still larger evolution. A similar distillation was carried out with alder.

It was deemed of interest in this experiment to obtain some idea of the amount of furfural produced. That furfural is formed during the distillation of wood at low temperatures was noticed by Heill (*loc. cit.*). The actual yield, so far as we know, has never been made the subject of experiment. Furfural is easily estimated by means of phenylhydrazine. A solution of that substance was standardised against a 1 per cent. solution of pure furfural in dilute methyl alcohol, using as indicator aniline hydrochloride, which gives a crimson colour with furfural. The reaction is a neat one, and permits of an accurate quantitative examination.

A quantity of alder, amounting to 148 grms., was distilled very slowly; in two hours the temperature of the bath was steady. The distillate was collected in portions. Gas began to come off slowly at 280°, and increased in rate up to 340°. The external temperature was then 324°, the inside temperature overtaking the outside temperature at about 300°. At 500° (for the temperature of the bath was subsequently raised) about 5 cc. of an almost colourless distillate was obtained.

The results are given in the following table :—

No.	Temperature.	Time.	Quantity of Distillate.	Furfural.	Acetic Acid.
		Hours.	Less than 1 cc.	Grms.	Grms.
1	200°	2	1.5	0.05	0.0
2	200°-230	2	1.5	0.00	1.28
3	230°-250	1 Min.	6.0	0.006	1.95
4	250°-270°	25	1.5	0.05	0.88
5	270°-290°	25	1.5	0.064	0.83
6	290°-310°	15	3.5	0.086	0.80
7	310°-320°	10	5.0	0.142	0.79
8	320°-330°	10	5.0	0.170	0.78
9	330°-340°	15	1.5	0.237	0.87
Totals.....				0.985	8.18

It is again evident that the yield of acetic acid increases towards the end of the distillation, bearing out the remarks which were made before.

Contrary to expectation, the furfural appears to be produced in larger quantity at the end than at the beginning of the distillation, and it amounts to the not inconsiderable quantity of 0.62 per cent. of the weight of the wood. The acetic acid forms 5.45 per cent. of the weight of the wood. This furfural does not appear in operations on the large scale, because it is destroyed in "liming" the methyl alcohol. When heated with an alkali, it is converted into pyromucate of the alkali metal, and furfuryl alcohol, a non-volatile syrup. Hence it remains in the residues as a tarry mass. It is however possible to obtain furfural in quantity by allowing the weak alcohol to deposit it as an oil, before rectifying over lime. In the course of some days a layer settles, which can be drawn off. Of course much still remains dissolved, which must be removed by "liming."

A matter of some interest is the amount of water contained in the wood. This water cannot be estimated by drying at 100°, for at that temperature the wood is partially

decomposed, and the escaping vapours do not consist wholly of water. Experiments were therefore made of drying the wood over sulphuric acid *in vacuo* for a month. The results are as follows :—

	Per Cent.
Oak.....	13.58 H ₂ O
Beech.....	11.60 ..
Alder.....	11.64 ..

Alder, when hought, is usually very wet, and dries very rapidly after it is sacked. It is interesting to note that after such drying it contains nearly the same percentage of hygroscopic water as oak or beech.

Such are the results of the first part of this research. To summarise them briefly :—

1. The distillation of oak, beech, and alder is accompanied by an exothermic reaction, having for its products charcoal,

carbon monoxide and dioxide, and methane, acetic acid, methyl alcohol, acetone, and furfural, together with certain methoxy-benzene compounds.

2. These substances appear to be formed from beginning to end of the distillation; their appearance at first is doubtless due to the rise of temperature at the exterior of the wood; but they are formed in largest quantity when the exothermic reaction sets in.

3. The proportions of charcoal and gas relative to the other products depends on the temperature of distillation; but a high temperature does not appear to diminish the proportion of acetic acid and methyl alcohol.

4. Different woods, while nearly constant in their yield of acetic acid, differ greatly in their yield of methyl alcohol, or at least of some product which yields carbon dioxide on oxidation with potassium dichromate and sulphuric acid.

The direction of further investigation is obvious. It is known that wood which has been stored for long, and has rotted more or less completely, gives much poorer yields of acid and spirit than seasoned dry wood; and we are now proceeding with the study of cellulose (cotton-wool) and of jute in order to ascertain the effects of such changes.

DISCUSSION.

Mr. BERTRAM BLOUNT asked whether it was customary, when working on a large scale, to carry out the distillation *in vacuo*. It appeared from the sketch illustrating the apparatus that the author of the paper had made his experiments *in vacuo*; and it seemed to him that the results would be considerably influenced by the absence of pressure. He would also like to know why Professor Ramsay classified wood as an explosive. Wood might be a substance which, on distillation, gave an exothermic reaction, but he did not think that it could legitimately be called an explosive on that account.

Mr. OSWALD HAMILTON said the authors' experiments indicated considerable differences between the amounts of methane produced at high and low temperatures respectively. He thought that the differences, observed by the authors between the amount of charcoal produced at high and low temperatures, were more apparent than real, for the charcoal produced at low temperatures probably contained some pitch. This was borne out by the authors' tables, where the sums of the charcoal and pitch, at high and low temperatures respectively, were practically the same. With regard to the sudden rise of temperature about 300° C. a similar phenomenon was observed in the distillation of coal-tar, during which process the mercury in the thermometer suddenly rose from 300° C. to over 360° C. Whether this was due to an exothermic reaction or not, he could not say.

Mr. C. F. CROSS thought that in describing wood as an "explosive" substance, Professor Ramsay had given particular point to a most important result. This property was a fair inference from the general physiological consideration of substances composing living tissues. In recent chemical literature the correlative term "chemical tension" had been much used, and the conception expressed by it had been identified as a necessary condition of substances which had to adapt themselves to a long series of intrinsic changes. The light which had now been thrown on the subject from an altogether unexpected source gave the question new emphasis; and with the term explosive the authors of the paper had given definite expression to a phenomenon which he (Mr. Cross) and others had recognised rather on *a priori* grounds. He would venture to quote from a review written by himself some years ago.

"The study of the chemistry of lignification and of the fate of moribund vegetable matter therefore proves the possession of a high degree of intrinsic energy by plant substances, and the tendency to retain this energy in the form of derived compounds in which the carbon is proportionately accumulated (*Nature*, 1885, p. 606)."

He would not refer at length to what Professor Ramsay had promised later on, namely, the further consideration of the results he had brought before the meeting; but he would emphasise one point. The authors had obtained no acetic

acid in the dry distillation of the jute fibre; whereas this acid was easily obtained by the action of hydrolytic agents. It appeared to be formed, together with furfural, from the cellulose β of the fibre—a "penta"-cellulose. It was premature to attempt to explain this negative result; but the hypothesis that lignification was a continuous process of conversion of the wood cellulose into this cellulose β and semi-aromatic products, might be taken into account by the authors in the prosecution of their investigations.

Mr. DAVID HOWARD would like to say a word in praise of the strong language used by Professor Ramsay. From a manufacturer's point of view, wherever there was a possibility of a spontaneous rise in temperature, a practical expression for an exothermic reaction, there was a danger of explosion. He had no personal experience in the distillation of wood, but certainly if he had to carry out the process described by the authors, he would look very carefully to his outlets before he began.

Mr. WILLIAM FOSTER referred to some notes of his own experiments on the destructive distillation of the carbohydrates, selecting those referring to dry sawdust from the wood of the coniferæ. The temperatures used in his observations were much higher than those employed by the authors, and were similar to those found in coal and shale distilling industries. One point had been made pretty clear, namely, that the amount of carbonaceous residue (coke) was practically constant when a substance was destructively distilled at temperatures called "high" and "low" by gas engineers. Great variations, however, occurred in the amounts of condensibles (tar and water) and gas. The quantity of gas both as to volume and weight was increased by augmented temperature, the quantity of tar and water being proportionately diminished. The quantities of charcoal (coke) from oak at high and low temperatures given in the authors' tables as 24 per cent and 33 per cent, respectively, showed differences greater than he had observed in destructive distillation proper. The following figures were obtained in three independent experiments with sawdust (dried):—

Charcoal (coke).....	21.97	21.17	21.05
Tar and water.....	32.29	31.69	27.52
Gas.....	43.81	46.64	50.93
	98.07	99.50	99.50
Gas obtained per pound (measured at 62° F. and 30 in.) in cubic feet.....	6.44	6.89	7.83

Each of the gases, marsh-gas and hydrogen, was present to the extent of about 18 per cent.; and the carbonic oxide and anhydride jointly measured more than 50 per cent. The free nitrogen was in no case more than 3 per cent. These figures were obtained after some considerable experience with an apparatus which had been devised for the purpose of accurately ascertaining the amount of each factor when the raw material operated on weighed 2 lb. or even more.

Furfural was abundantly produced in the distillation of the carbohydrates at high temperatures, the tar from such bodies being probably as convenient a source of supply as any given in the text books. Acrolein and allyl alcohol were also, he believed, to be found under such circumstances, although he had not separated them from the other products as he had done in the case of furfural.

Mr. WARREN SMITH had listened with much interest to the paper, although he had had the privilege of seeing the experiments made in University College. He would like to add his word of support in favour of the word "explosion," as signifying an exothermic development, and he would like also to point out the very considerable difference between that action and the so called "break" in coal-tar distilla-

tion. No exothermic phenomenon was concerned in that "break," for when the distillate reached a certain degree of temperature there was a cessation of the distilling process until the temperature of about 110° C., at which the break commenced, had been increased by extra firing to about 180° C., when distillation recommenced. In 1871 he had the management of both a coal-tar and a wood distillery, so that he could look upon himself, to some extent, as an old wood distiller. In that year he communicated a paper to the Chemical Society on the subject of the distillation of wood (J. Chem. Soc. 1871, 1101—1108.) He had demonstrated, by the testing of samples taken at different stages of the process, that the amount of acetic acid gradually increased in a 12 hours' distillation, up to the seventh hour after the commencement, and that thereafter a gradual fall took place. During the first six hours, the specific gravity gradually increased from 1.01 to 1.017, and then in one hour rose to 1.03. At this point the specific gravity remained constant during the remainder of the distillation. After reaching the stage at which the specific gravity had increased to 1.03 the amount of tar distilling over was found to have reached the highest proportion so far attained. After the eighth hour the proportion of tar increased steadily. Professor Ramsay and Mr. Chorley had also found that the proportion of tar became increased if the temperature of distillation was raised. Towards the end of the distillation the temperature would naturally be higher, and for that reason he would expect, *a priori*, that the quantity of tar furnished at the latter stage would be higher. In working wood retorts on a large scale, he had never noticed sudden rises in temperature. There was no outward manifestation such as would strike a workman; and he did not think that it was considered necessary to draw the fires, or to open the fire-doors. This was his experience, and he had since learnt it was the experience during 40 years of his friends Messrs. Robt. Rummy and Co., of Manchester. But it was only fair to add that in these cases oak crop wood and timber in fairly large pieces were carbonised, whereas the authors used their wood cut up very small, and, moreover, it seemed well dried. In the first case there would be small surface and slow action, in the latter, large surface and rapid developments. He did, according to his own experience, recollect that a few hours after commencing, at the period, probably, at which most of the water as moisture in the wood was driven off, there was a much larger flow of gas than had previously been the case. With regard to wood charcoal, he believed that it was never absolutely charred. The charcoal, when transferred from the ovens to the cooling vaults, generally had a quantity of water thrown in after it in order to choke out any possible combustion. Being saturated in this way with aqueous vapour and moisture, and having cooled, the vault doors were opened, and the charcoal conveyed in iron wheel-barrows to the shed. This charcoal was exceedingly liable to burst spontaneously into ignition in the shed, and for this reason great caution had to be exercised. In this connexion he would remind the meeting that in a recent communication to the Society of Arts Journal with regard to coal, Professor Vivian Lewes had stated that it was found that coal caught fire spontaneously even in the absence of pressure, when, for example, a quantity of coal powder in a biscuit tin was maintained at a temperature of 100° C. for some little time. These were simple cases of exothermic action, or "explosion," and doubtless that of the charcoal described was quite analogous to that of the wood at a less advanced stage of decomposition, as described by the authors. It was, for the most part at least, the "explosion" breaking out anew, albeit under slightly modified conditions.

As to the utilisation of wood creosote, an American member, Dr. Franklin S. Clark, distilled forest-wood very largely in Wilmington, N.C., principally to obtain wood-creosote for the antiseptic treatment of wood for railway sleepers, and for especially resisting the attack of the sea-worm (*teredo navalis*). (This Journal, 1890, 1005).

He would like to point out that the late Mr. E. T. Chapman found hydrogen in wood-gas (Chemical News, 1871, 105. See also *ibid*, pages 91—93).

Mr. A. G. GREEN inquired whether Professor Ramsay's numbers for the methyl alcohol were obtained by oxidation of the total alcoholic mixture or whether this was submitted to a preliminary fractionation. He thought if this was done the acetone might be determined by conversion into iodoform, and the difference would give the methyl alcohol. He gathered that the authors had not as yet determined the acetone.

Mr. B. BRIGGS remarked that in this country, chiefly South Wales and Scotland, an important quantity of wood spirit was turned out; but the great difficulty in England was that manufacturers were hampered by the Government from treating the products of wood distillation in the way in which the Germans dealt with them. If methyl alcohol were made in England, the duty upon it would be 17s. or 18s. a gallon, and with that burden placed upon its manufacture, it was impossible to make it a paying industry, or to compete with German manufacturers in producing the colour for which it was employed. He had endeavoured to get the authorities to amend that state of affairs, but he was sorry to say that he had not been successful. The question of wood distillation was a very interesting one, but he was afraid that in this country, till some change was brought about, it must be considered as a dying industry.

Professor RAMSAY, in reply, said that there had been some misunderstanding, perhaps, because he had not made himself quite clear. The apparatus explained itself. After the air had been pumped out of the apparatus, the distillation commenced, and the gases produced soon raised the pressure again. When pressure had become normal, the gases were allowed to enter the gas-holder. Mr. Hamilton was quite right in his remarks about charcoal. The authors of the paper had found, after further research, that undoubtedly the resulting charcoal contained a large quantity of gas. Distillation on the large scale usually lasted about 12 hours, and on the small scale from $2\frac{1}{2}$ to 3 hours, so that six hours on the large scale would correspond to three on the small. It had been noticed on the large scale that there was an exothermic reaction. One manufacturer he knew of had been in the habit of burning the gas, but this course was not of much use, because the gas came at the wrong time, and it was not wanted at the end. With reference to the question of creosote, he would like to ask Mr. Watson Smith whether it was utilised in this country.

Mr. WATSON SMITH replied that it was only utilised in the United States.

Professor RAMSAY, continuing, said that he would like to add one point, namely, with regard to the temperature of distillation on the large scale. It was a mere matter of guesswork. It was somewhere between 400° and 500° , probably about 425° . A fairly accurate conclusion could be arrived at by comparing the yields of charcoal and gas on the large with those on the low scale.

NOTES ON SOME INDIAN GUM SAMPLES OF KNOWN ORIGIN.

BY DR. S. RIDEAL.

DURING an investigation by Mr. Youle and myself on the relative value, for commercial purposes, of some modern substitutes for gum arabic (this Journal, 1891, 610) our attention was naturally drawn to the characteristic properties of those Indian gums which are brought to the London market.

The favourable results obtained from the samples which were then examined for a variety of purposes led us to devote considerable attention to this class of gum, and we found that, as a rule, a good mucilage could be reasonably expected from them, as seldom did the insoluble portions reach a very high percentage.

We advocated the use of Ghatti gum for pharmaceutical purposes at the British Pharmaceutical Conference at Cardiff during the autumn of last year (Year Book of Pharmacy, 1892, 405, *et seq.*) and have since found that many manufacturers have been induced to give these gums a further trial. Quite recently the Bombay correspondent of the "Chemist and Druggist" (March 19th issue) has again drawn the attention of English consumers to this article: he says, in speaking of Ghatti gum (finest sort), "This gum is exclusively used in India by pharmacists. The English druggist has apparently not yet found out the value of this drug, which can be had in all qualities, and is (in the best grades) double the strength of Turkish gum acacia." These remarks, whilst confirming the favourable opinion already formed, naturally lead one to imagine that in India we have gums which are very suitable for many classes of work in this country. Unfortunately the gathering of gum in India is not yet carried out with any system and little is known as to which gums would yield the best price in England. That which is at present exported is named "ghatti," "anrad," &c. from inspection, and sorting the gums when once they are mixed is a laborious and expensive operation. We thought that it would be interesting if gums of known origin from India could be sent in small quantities to this country for the purpose of examination, and that by so doing light would be thrown on the best localities for the finest sorts of gum.

Through the kindness of Professor Pedler, of Calcutta, I have had placed at my disposal a series of gums which have been collected by the Government department, from trees of known botanical origin, and in most cases from known localities, and it is the purpose of this note to briefly describe the physical and chemical properties of these gums. Amongst these the most important is the—

Acacia Arabica Gum.—In India the tree is known as the Bahul tree and abounds all over Northern India, where it is prized more for its wood, which is used for fuel and timber, and its bark, which is of value for tanning purposes, than for its gum. The yield of gum too, is very small as compared with the yield from the same tree in other parts of the world, *e.g.*, in Arabia and Egypt. This small yield is probably due to the climatic difference of India, as the production of gum requires a dry atmosphere like that which abounds in the deserts of Arabia and Africa, the true home of the gum arabic.

Where such a climate exists as in Rajputana and Sind, the tree yields quantities of gum, but not sufficiently large to form an important item in the export trade. The indigenous product is merely used for home consumption in the interior of the country. The requirements of the seaport districts being met by the imported gum, very little of it finds its way to the seaport for export. The gum exported from Bombay to Europe is chiefly obtained from the Red Sea ports, and it is more or less adulterated with the Indian product. The Indian gum is inferior in quality to that obtained from Arabia and Africa. The colour is usually dark and it is frequently mixed with gums of other trees, and often these admixtures contain fragments of gums which are insoluble in water. In India, acacia gum is used for medicinal purposes as well as in the preparation of sweetmeats. The true Indian gum sells at 15 to 25 rupees per hundredweight, according to quality. It is reported that barren trees can be made to yield gum by inoculating it with gum from another tree, but, as far as I have been able to ascertain, no systematic experiments in this direction have as yet been tried. The samples of gum acacia sent from India consists of very hard, light, brown, irregular masses, without any marked taste or smell. They swell up in water to a pale-brown jelly and finally are completely soluble. They give a mucilage which is fairly adhesive, and with most reagents give characteristic reactions, while Ghatti gums gave negative results.

On analysis the sample gave 16.38 per cent. moisture and a fairly high ash (4.46). Its solution was very viscous, and it contained the smallest quantity of nitrogen of any of the samples examined. O'Sullivan, in a recent paper, has drawn attention to the presence of some nitrogenous substance in samples of Gedda gum, but apparently it exists in too small a quantity for isolation. On the other hand,

it may be that the gum acid is itself sometimes partially converted into an amido compound. The quantity of nitrogen present in all these Indian samples is recorded in the table, but it is difficult to draw any conclusions from the numbers obtained.

Acacia Catechu.—From this tree the catechu of commerce is obtained. It yields a gum of a pale yellow colour, and like the gum obtained from the Babul tree, is usually completely soluble in water. Some of the specimens are almost white, and apparently in India the gum from these trees is usually of better quality than that obtained from the tree *Acacia Arabica* when grown in the same place. It is, however, not procurable in large quantities. In point of fact, none of the Indian gums at present can be obtained pure in such quantities as to form a trade article by itself; hence Indian gums imported to this country are usually of the mixed character already referred to. The sample of a case of catechu examined came from Surat, Bombay, and occurred in light brown translucent angular masses. It left a slight residue insoluble in water. The specimens at my disposal were slightly musty, so that the mucilage obtained from it had not a very good adhesive value. Its viscosity was also small, and it had a fairly low ash. The complete figures of this and the other gums are given in the table at the end of these notes.

Acacia Farnesiana.—This tree yields a large quantity of gum, and is also found in the mixed gums imported to this country. The tree grows very freely in Sind. The sample examined was furnished by the Forest Department of the North-West Provinces, and had a pale red colour. Mr. Baden Powell has described the gum as occurring in "dark conchoidal masses translucent and transparent at the edges. Some of the pieces are much whiter." Our samples came from Bahraich and Oudh, and were mixed with bark. It dissolved completely in water, forming a deep brown mucilage which had very poor adhesive property. It did not darken on warming with normal soda, gave a slight brown precipitate with ferric chloride, and threw down a copious precipitate with alcohol. It contained 15.45 per cent. of moisture; ash, 2.08 per cent., and nitrogen, 0.061 per cent.

Acacia Ferruginea.—This gum occurs in brown irregular masses very similar to the former sample (*A. Farnesiana*). It is entirely soluble in water and is fairly adhesive. It differed from *A. Farnesiana*, in darkening with normal soda, but in other respects was very similar in character. Its moisture was high, 17.09, its ash 3.22, and it contained the highest quantity of nitrogen, 0.082, of any of the samples. Our sample came from Panchmahals, Bombay.

Acacia Leucophloea.—This tree is generally found in Central and South India. It yields a gum which is usually as white as the true gum arabic. It was exhibited at the Colonial and Indian Exhibition and was described by Dr. Fre as "gum bassora." The sample examined came from Saltara, Bombay. It consisted of light brown irregular masses with a slight marked taste and a peculiar aromatic odour. It dissolved entirely in water to a light brown liquid, and gave a fairly adhesive mucilage. In this respect therefore our sample differed from the sample described by Dr. Fre, but it contained a certain amount of metarabin arabin, as it gave a gelatinous precipitate with ferric chloride. Normal soda darkened the solution faintly. It yielded a white ash, gave a very viscous solution, and contained 14.65 per cent. of moisture.

Acacia Modesta.—This tree yields beautiful, clear, transparent lumps of reddish gum. I learn that it is largely used by calico printers in India. The sample examined came from the Punjab. It had an aromatic odour, dissolved completely to a pale yellow liquid, and gave a fairly adhesive mucilage. It turned yellow with normal soda, became solid on the addition of ferric chloride, and gave a thick white precipitate on the addition of alcohol. Basic acetate of lead also gave a thick white precipitate with the mucilage, and the contents of the tube became a solid mass. The sample had a fairly low ash, 2.91, contained 16.70 of moisture, and yielded a solution of medium viscosity. These were the only true acacias of which samples were sent, but in addition there are other gums

yielding trees, of which several samples were submitted, of which the following is a short account:—

Albizia Amara.—This tree is found in South India and yields a red coloured gum very much like the best kind of Indian acacia gums. The sample examined came from Cernbatorea, North Madras. It had a fragrant smell, was entirely soluble in water yielding a yellowish brown liquid, and was a very good adhesive gum. The liquid became thick on standing with ferric chloride, turns bright yellow when warmed with normal soda, and gave a slight precipitate with stannous chloride. The viscosity of the solution was high, being 19.28 times that of water. It contained 11.22 per cent. of moisture, 3.20 per cent. of ash, and had a very small percentage of nitrogen.

Anogeissus latifolia.—This tree is found all over India, and yields very large quantities of gum, which is also extensively used in calico printing. It is whiter than most acacia gums, but seems to possess far less adhesive power. The samples examined came from Secunderabad, near Hyderabad, and occurred in large spherical nodules. These lumps swell up to a great amount on the addition of water, consisting almost entirely of metarabin, very little liquid being strained off. It is useless as an adhesive gum. Mercuric chloride gave a white precipitate; with borax the solution became thicker. Ferric chloride darkened the liquid, showing the presence of tannin. It turned yellow with normal soda, and gave a thick white precipitate with alcohol. The gum yielded a very small ash, 1.28. The solution was very feebly viscous, viscosity Z equal to 320. It was certainly the poorest of any of the gums examined.

Banhinia retusa.—This gum is obtained from the North-West Provinces and Oudh. It resembles Indian gum acacia in colour and is soluble in water to a light-brown liquid. The sample sent was in too small a quantity for many experiments. It yielded 3.28 per cent. ash and 10.49 per cent. moisture.

Banhinia variegata.—This gum resembles the former, but the sample examined from Garhwal seemed to be a mixture, as amongst the dark brown masses were lighter coloured particles. It dissolved, however, entirely in water, forming a reddish-brown liquid. It had a slight aromatic smell, turned brown with the addition of normal soda, gave a thick flesh-colour precipitate with basic lead acetate, and turned solid on the addition of ferric chloride. Alcohol also threw down a thick flesh-colour precipitate. It yielded a solution which was of very poor viscosity, and is useless as an adhesive gum. It had a low ash, 2.51 per cent., and contained 13.63 per cent. of moisture.

Buchanania latifolia.—This is described as a clear resinous gum, but it resembles the true gum acacia in appearance, being nodular and covered over with fissures. It dissolves readily in water, forming a pale yellow liquid, but this solution is only very slightly adhesive. It has a sweet taste, a faint aromatic smell, and gives, with ferric chloride, a dark brown jelly immediately; basic lead acetate gives a thick white precipitate; mercuric chloride converts it into a jelly, and it turns bright yellow on warming with normal soda. It yielded 4.65 per cent. ash, which contained a trace of iron, contained not less than 20.73 per cent. moisture, and had a viscosity value Z equal to 0.694. The sample came from Betut, Central Provinces.

Odina Wadler.—This tree yields a large quantity of gum during the rainy season. This is white when it hangs on the tree, but becomes dark when it falls on the ground. The gum is not much valued in India, but is sometimes used in calico printing. A sample from Secunderabad, near Hyderabad, was examined. It occurred in dark brown lumps, had undergone slight fermentation, having a sour taste and smell. It partly dissolved in water, the remainder swelling up. With ferric chloride it gelatinised at once. It turned very dark on warming with normal soda; gave a thick white precipitate with basic lead acetate, and borax thickened the mucilage. It contained 18.09 moisture, and 3.52 ash. The solution was of very feeble viscosity.

Terminalia Tomentosa.—Our sample of gum of this tree also came from Secunderabad. The tree is stated to yield gum only in small quantities. The specimen examined was

very pale yellow in colour, the lumps being very glossy and transparent. Although in appearance so good, it only partly dissolved in water. The soluble portion formed a fairly adhesive mucilage, but it gelatinised and darkened in colour on the addition of ferric chloride. It was thickened

with borax, and turned pale yellow on warming with normal soda. This gum was further characterised by an exceptionally low ash, 0.66 per cent. Its solution was of very feeble viscosity, and the solid had a high specific gravity 1.904.

TABLE I.

	Moisture.	Ash.	Viscosity.		Specific Gravity.		Nitrogen.
			η .	z.	10 per Cent. Solution.	Of Solid.	
<i>Acacia leucophloea</i>	14.65	4.12	0.1371	1.106	1.020	1.599	0.054

<i>Olinia wadiei</i>	18.09	3.52	0.04415	356	1.013	..	0.054
<i>Terminalia tomentosa</i>	17.59	0.66	0.03510	525	1.017	1.904	0.039
<i>Buchanania latifolia</i>	20.73	4.65	0.0849	694	1.018	1.640	0.039

TABLE II.

Gum.	Colour.	Taste.	Smell.	Solubility.	Adhesiveness.
<i>Acacia leucophloea</i>	Light brown, irregular	Marked	Peculiar odour	Entirely soluble to light brown liquid.	Fair.
<i>Acacia catechu</i>	Light brown, translucent, angular.	Slightly sour	Sour	Partly soluble to colourless liquid.	Very slight.
<i>Acacia ferruginea</i>	Brown, granular, containing bark.	Nil	Faintly sour	Entirely soluble to brown liquid.	Fair.
<i>Acacia farnesiana</i>	Brown, irregular, not all the same colour.	Slightly sweet	Nil	Entirely soluble to brown liquid.	Very slight.
<i>Acacia modesta</i>	Light brown, irregular	Nil	Peculiar odour	Dissolves completely to yellow liquid.	Fair.
<i>Acacia arabica</i>	Very hard light brown, irregular.	Nil	Slight mouldy smell.	Swells up to pale brown jelly.
<i>Acacia ?</i>	Brown, irregular	Nil	Very faint odour.	Partly soluble to light brown liquid.	Slight.
<i>Albizzia amara</i>	Light brown	Nil	Sweet odour	Entirely soluble to yellowish brown liquid.	Very good.
<i>Anogeissus latifolia</i>	Light brown, partly spherical.	Nil	Nil	Swells up to grey mass. Little liquid strained off.	Useless.
<i>Bauhinia variegata</i>	Dark brown, containing lighter particles.	Nil	Very faint	Entirely dissolves to reddish-brown liquid.
<i>Buchanania latifolia</i>	Yellowish brown; bark adhering to it.	Sweet	Faint	Entirely soluble to pale yellow liquid.	Slight.
<i>Olinia wadiei</i>	Dark brown	Sour	Sour	Partly dissolves.
<i>Terminalia tomentosa</i>	Translucent yellow	Nil	Smell like leather.	Partly dissolves; soluble portion pale yellow.	Fair.

The more important physical and chemical properties of the gums examined are tabulated above, but, in addition, the following summary of the behaviour of a 10 per cent. solution of the gums towards the following reagents may be of interest:—

1. When warmed with an equal bulk of normal soda, *A. farnesiana* and *A. arabica* did not darken in colour;

A. modesta, *Albizzia amara*, *Anogeissus latifolia*, *Buchanania variegata*, and *Terminalia tomentosa* turned yellow; whilst the other gums darkened considerably.

2. A saturated solution of borax only appreciably thickened the mucilages from *Anogeissus latifolia*, *Buchanania latifolia*, *Olinia wadiei*, *Terminalia tomentosa*.

3. Mercuric chloride gelatinised the mucilage from *Buchanania latifolia*, and gave precipitates with *Anogeissus latifolia* and *Terminalia tomentosa*.

4. Stannous chloride gave no reaction with the solutions of *Acacia leucophloea*, *A. ferruginea*, *A. farnesiana*, *Buchanania latifolia*, and *Odinia wadiei*.

Ammonium oxalate, basic lead acetate, and alcohol gave precipitates more or less copious with all the samples examined, and, as already mentioned, ferric chloride gelatinised many of the acacia gums as well as those obtained from other trees.

Traces of phosphoric acid were found in the ashes of all the samples with the exception of *Acacia catechu*, *A. leucophloea*, *A. modesta*, and *Bauhinia variegata*, and, although material was insufficient for an estimation, it was apparently present in fair quantity in the ashes of *Acacia ferruginea*, *Bauhinia retusa*, and *Terminalia tomentosa*.

It will further be noticed that nitrogen was found in all the gums examined, varying in amount from 0.031 to 0.082 per cent.

From this investigation it will be seen that the Indian gums vary very considerably in character, and as this examination is by no means exhaustive, I hope that further attention will be directed to the subject. Statistics are wanted as to the best localities for the growth of these different trees, and also the climatic conditions which occur in those districts. No doubt the geological structure of the country also materially influences the quality of the gum yielded by the tree; and if this paper will lead to the work being carried on in India, there can be no doubt that we shall eventually obtain from that country gums of known value and suitable for many industrial purposes.

DISCUSSION.

MR. PETER MACEWAN said that the mistake made by those who had taken up the question of gum arabic and its substitutes was that they had not persevered with the subject. He was pleased to notice that Dr. Rideal persevered, and there was need for that as the various gums known as gum arabic differed very much, and not only did the gums from different countries differ, but those from one country varied considerably according to the nature of the season. He trusted, therefore, that Dr. Rideal would still continue his research.

MR. WATSON SMITH said that he had examined the waste liquors of the sulphite cellulose process for preparing wood pulp, and had found a considerable amount of gums of very adhesive nature. On evaporating these liquors, the same sickly and disagreeable odour was developed that was characteristic of the vapours proceeding from the works when the contents of the digesters were discharged. So long as water remained and the gum existed in solution, the smell remained. On evaporating to dryness the gum possessed no smell, but on re-dissolving in water the solution smelt as disagreeably as ever. So far, any method he had found efficacious in destroying the odour also seriously interfered with the gums.

DR. RIDEAL, replying to Mr. Watson Smith, said that he would be very glad if he would send him a sample of the substance referred to. He agreed with Mr. MacEwan's remarks.

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—Vice-Chairman: E. Carey. Committee: J. Campbell Brown, Jos. C. Gamble, G. Schack-Sommer, and A. Norman Tate.

Meeting held Wednesday, 2nd March, 1892.

MR. A. NORMAN TATE IN THE CHAIR.

ON AGRICULTURAL FERTILISERS AND FEEDING STUFFS AND THE BILL NOW BEFORE PARLIAMENT TO AMEND THE LAW WITH RESPECT TO THEIR SALE.

BY DR. GUSTAF SCHACK-SOMMER.

ON previous occasions I have had the honour of appearing before you as an advocate of the cultivation of beetroot in England and Ireland for the purpose of sugar manufacture, as that industry is conducted on the Continent, and more especially in Germany and France. The subject which I wish to bring before you to-night may be regarded as somewhat remotely connected with that of beetroot cultivation, it relates to fertilisers and animal food stuffs. You are no doubt aware that a Bill was introduced by Mr. Chaplin into the House of Commons last July in his new office as Minister of Agriculture, to regulate the trade in these articles. The Bill runs much upon the same lines as the Food and Drugs Act, and, as it is virtually an extension of this Act which relates to the adulteration of food, and is an attempt to prevent the adulteration of fertilisers and feeding stuffs prepared upon chemical principles, I think the subject should have a strong claim upon the attention of societies such as this. Manufacturers (and more especially those whose business is conducted on scientific principles) should be afforded an opportunity not only of criticising the proposals of the Legislature, but when advisable, of bringing pressure to bear with a view to their amendment. Under these circumstances it is clearly our duty, in the best interests of the community, to make our weight as a society felt, by offering such suggestions as those I have the honour of submitting to-night, and which I hope may be speedily supplemented by others coming from those who possess more extensive scientific knowledge and larger practical experience.

Before proceeding further it may be well to recite the provisions of the Fertilisers and Feeding Stuffs Bill, and of course I shall not trouble you with its legal phraseology but merely with a brief *résumé* of its clauses.

Taking these in their order we find a penalty of 20*l.* is imposed for the first offence and 50*l.* for each subsequent offence, when a conviction is obtained for selling adulterated fertilisers and food stuffs for cattle; but that the seller shall not be liable if the article purchased was not used for the purpose for which it was sold: yet that it shall be no defence to allege that the purchaser, having bought only for analysis, was not prejudiced by the sale; that an invoice must be given to each purchaser specifying the nature and quality of the article sold, and in the case of a compound article its material ingredients with the percentage or approximate percentage of each; that any material inaccuracy in the description in the invoice shall render the vendor liable to the before-mentioned penalties; that a seller shall not be liable if he can prove that he sold the article as he received it; that a seller who can prove this, but who is convicted, shall be able to recover the fine with all costs and damages either from the manufacturer or from the dealer from whom the article was purchased in the first instance; and, that the Board of Agriculture may appoint a chief analyst.

In this Bill I may remark that I do not find any provision for punishing a dealer who sells feeding stuffs which, through decomposition or because of their composition, or for any other reason, may be unfit for the purpose for which they were sold. The Bill, too, should be so amended as not to unnecessarily harass manufacturers in the business, or place obstacles in the way of honest dealing in such articles. Take, as an example, the case of a manufacturer who, having discovered a by-product which contains one or more of the four principal fertilisers, mixes this by-product with other substances containing the other necessary fertilisers. Why should he be compelled to divulge the secret of his manufacture by describing it on an invoice as proposed in the Bill? In my opinion all that is necessary is a guarantee that the article sold contains certain proportions of nitrogen, phosphoric acid, potassium and lime. In the case of feeding stuffs a very large trade is done in mixtures, and as long as those are guaranteed to contain stated proportions of good, sound, digestible food, including protein, fat, sugar, and non-nitrogenous extractable matter, there is clearly no necessity to require the secrets of manufacture to be published in an invoice for the benefit of trade rivals. What is of great importance is, that farmers should be taught clearly the elementary chemical principles underlying the successful preparation both of manures and feeding stuffs, so that they may be able to select the best goods for their purpose. This, of course, means technical education for farmers, and when it is achieved there will be less necessity for special legislation for their protection.

Glancing at other countries we find that while France and Belgium have special laws affecting this subject, a different state of things prevails in Germany and Austria. The Governments of the latter countries, after going fully into the question, have arrived at the conclusion that by private arrangement between manufacturers, dealers, and purchasers, they are able to protect one another, and this has resulted in the establishment of a set of rules which have to be adhered to by the members of such an association, consisting of the manufacturers, dealers, and buyers of feeding stuffs and fertilisers. These rules all aim at one object, and that is the protection of the small buyer. Buyers on a large scale are astute enough not to begrudge the small fee for testing the goods they buy, and so assuring themselves that they get full value for their money. The small buyer on the other hand has to be protected partly from want of technical instruction, for it may be presumed he rarely knows of agricultural testing stations and laboratories, or if he does he distrusts them, and partly perhaps from finding that however small the fee, it increases the price of his purchase, and for this purpose the following rules were established. They state that the article must be sold in its original bag or package with the following information written or printed legibly upon it:—

- 1st. The maker's name or that of the factory.
- 2nd. The article it contains, and whether in powder, granular, or in lumps.
- 3rd. What ingredients are guaranteed.

A dealer who had bought a one hundredweight bag could not repack it into two half-hundredweight bags, but in the case of a demand for the latter would have to get the smaller size from the manufacturer. The advantages of these rules are so obvious that I must apologise for dwelling on them. Any honest manufacturer or dealer will court being checked by an agricultural chemist, and will most likely contribute to laboratories which not only guard the purchaser, but at the same time the interest and reputation of the manufacturer.

As far as this country is concerned I think it is safe to assume that if adulteration takes place it will arise through a system of fraudulent repacking by greedy middlemen, a species of cheating, which the rules I have mentioned make impossible on the Continent. In such a case, should a dishonest dealer imitate the bag or package of a manufacturer, or re-pack and adulterate the contents, he would run the risk of being found out, and of course, on conviction, could be punished by the law as it now stands. What we want, in fact, is not an alteration of the English law but the introduction of the German and Austrian rules of sale. The weak point in the situation, as far as the chance of the adulterating middleman being found out is concerned, lies in the absence of testing stations and laboratories in connexion with the various agricultural societies, as well as of travelling teachers to give the farmers the technical instruction which they stand so much in need of. An ideal system, if I may mention such a thing *en passant*, to a practical society, would be for the agricultural societies of each district to form themselves into co-operative associations for the purpose of buying feeding stuffs and fertilisers in large quantities, and distributing them amongst their members, and retaining a chemist well versed in botany, and employing teachers to travel in the district to impart instruction. I have been told that such a combination has just been formed in Yorkshire, and the Agricultural and Horticultural Association, Limited, in London, generally called the "One and All," have done much useful work in that direction for some time past.

Even on the Continent, with their rules of sale, and their chemical testing stations and laboratories, they have not by any means attained perfection, for Professor Maercker and others have expressed an opinion that the agricultural laboratories in organisation and methods of analysis are not yet sufficiently advanced, especially in the matter of determining the purity of articles. That being the case on the Continent, matters are of necessity very much worse in this country, where, to the best of my knowledge there are only two agricultural testing stations and laboratories, viz., one at Rothamstead and one at Aberdeen; perhaps this may seem a small matter to those who believe that it is easy for the purchaser of food stuffs to ascertain that they contain a guaranteed amount of fat, or nitrogenous substance, and in the case of fertilisers to obtain satisfactory guarantees of the presence of a certain preparation of nitrogen, phosphoric acid, or potash. The difficulty is, however, for the purchaser to protect himself against such articles as contain injurious matters in addition to other innocuous materials which may have been purposely added, or occur accidentally through careless manufacture, or by using unsuitable or inferior raw material.

With the help of such trade rules as I have already told you are in force in Germany and Austria, there would be little necessity for legislation of any sort to prevent adulteration. Agricultural societies and their journals should constantly bring such regulations under the notice of farmers, and warn them against buying fertilisers which were not delivered in accordance with such regulations.

What these regulations are you will perhaps allow me to describe a little more in detail, and I hope in doing so as briefly as possible I shall not try your patience. The bags containing the fertiliser must be branded with—

1. The name of the factory where the fertiliser was made.
2. The commercial name of the article; and
3. The percentage of each important constituent.

The bags should contain even weights, say 56 lb., 1 cwt., or 2 cwt.

I have prepared a table showing what constituents should be guaranteed in fertilisers. *Phosphoric Acid soluble in*

water in superphosphates, Thomas slag; precipitates, bone ash, Baker guano.

N.B.—If these manures are valued and paid for according to their contents of soluble and insoluble phosphoric acid, then, of course, the percentage of both will have to be given.

Phosphoric acid soluble in water and all the nitrogen (N) should be stated in bone meal, fish guano, flesh meal, Peruvian guano, and ammoniacal and nitrogenous superphosphates, horns and other residue of tanneries.

Nitrogen (N) in blood meal, germ meal, nitrate, &c.

Potash (K_2O) in kainite and other potassium salts.

When samples are drawn they must be taken by the buyer or his representative, if possible in the presence of the seller or sender, or his representative, on the quay, or at the station, within two days of arrival at destination.

It would be very desirable if we could formulate on similar lines conditions for the sale of *feeding stuffs*, but unfortunately it is not so easy as in the case of fertilisers, for there are many more factors to reckon with. In feeding stuffs we could not remain content with a declaration that they contained a certain proportion of protein, fat, sugar, and extractable non-nitrogenous matter, for it is essential to know how much of the protein is digestible. What is also important to learn is not only whether it is unadulterated in the general sense of the term, but whether the food is clean and wholesome. The introduction of an obligatory guarantee as to contents and quality is of the highest importance both to agriculturists and manufacturers. A certain reasonable minimum figure should be fixed for the percentage of fat separately for the various feeding stuffs and the same for protein. In a letter which I received from Professor Dr. Maereker this morning, he communicates the fact to me that at a recent meeting in Berlin the representatives of the German Agricultural Boards and of the experimental stations have come to an agreement with the dealers in feeding stuffs to give a separate guarantee for both "*fat*" and "*proteine*" in future. And none below this percentage ought to be allowed to be sold. Oilcake, for instance, varies from 10 to 20 per cent. in fatty matter, according to the amount of pressure used in the manufacture, and as the fat is not only valuable itself but further aids the animal in digesting the other ingredients, it is really the most important element to be taken into account when estimating the value of a feeding stuff. A higher percentage of fat therefore might be paid for on a sliding scale, on the system which has proved so successful in the sugar industry. Let me here point out that the agricultural experimental stations and laboratories in Germany and Austria allow a latitude of one and a half per cent. for protein tests, and of one half per cent. for fat tests, as a margin for errors in testing. It would be difficult to formulate the exact extent to which a guarantee could be given as to the good and healthy condition of a feeding stuff and its freedom from foreign, injurious, valueless, or indifferent ingredients, but each invoice should include the guarantee upon which the article was sold. These guarantees, however, are not all-sufficient. The farmer should have such technical knowledge as would enable him to choose the best feeding stuffs and fertilisers for his particular purpose; yet how many farmers possess this necessary knowledge? It may therefore possibly be useful if, with your permission, I submit a few observations with regard to the most important cattle fodders, and the nature of the most frequent adulterations.

Artificial feeding stuffs include bran, feeding meals and cakes, by-products from distilleries and breweries, and last but not least those also of beetroot sugar factories.

Bran is very nutritious in consequence of being inseparable from the harder outer part of the real grain which contains much gluten. Its feeding properties are protein, of which wheat bran may contain up to 14 per cent., and fat, 4.9 per cent. The woody fibre, which is the valueless portion, is in the best kind of wheat bran only about 5.5 per cent., whereas in buckwheat bran, with 10 per cent. protein and 2 per cent. fat, the woody fibre is 38.2 per cent., and pea-kin bran with 8 per cent. protein and 25 per cent. fat, the woody fibre is 43.7 per cent. If the

bran has not been properly stored it gets mouldy, and this can be detected by the microscope which shows the fungi, as well as by the disagreeable odour. In that condition, of course, it is unfit for feeding purposes, but this is more easily guarded against than the danger arising from the addition of such weed seeds as are absolutely and actively injurious. Among these are ergot (*sclerotium clavus*), corn cockle (*agrostemma githago*), darnel or bearded ryegrass (*lolium temulentum*). Moreover sand, slate, gypsum, husks of oats, rice and other grains, and sometimes as much as 10 per cent. of water is added to increase the weight.

Of feeding meals the best known perhaps is rice meal, which ought to contain about 11.5 per cent. fat, and 46.1 per cent. soluble non-nitrogenous contents. This is often adulterated with its own or other husks, as for instance pea-skins which are absolutely without any nutritious value; also with chalk up to 22 per cent., with sand and gypsum up to 20 per cent., and from 15 per cent. to 20 per cent. of sulphate of barium. Linseed, cotton-seed, and other meals are simply ground cakes after the oil has been extracted from the respective seeds. Linseed meal is often adulterated with the seeds of gold of pleasure, cabbage, rye meal, and groundnut meal, clover seed, clover-seed chaff, coffee kernels, mustard seeds, and sand and soil up to a total of 48 per cent. It is also adulterated with the seed of plantain, dodder, garlic, mustard, and castor, any of which give the cattle colic, with the result that not infrequently they die. Meat feeding meal is a good and nonriching feeding stuff, containing 11.14 per cent. of fat, and is mostly made in Fray Bentos by Liebig's Extract of Meat Company. It has happened before now that stuff sold as this, or as a similar article, contained no meat substance whatever, but turned out to be a mixture of rubbish from tanneries such as glove and calf leather, with bran and about 5 per cent. of alum. Oilcakes are of the highest feeding value, and contain a large amount of protein, in the groundnut cakes as much as 42.8 per cent., and a varying quantity of fat according to the greater or less pressure used in extracting the oils. These oilcakes are sometimes mixed with sand, stones, and other rubbish to make weight, but this does not happen so often as does adulteration with less valuable and sometimes really harmful products. For instance, so-called German rape cake is very often made almost entirely of the unwholesome garlic mustard seed, which for that purpose is specially imported from Russia. Groundnut cake is adulterated with castor-oil seed, castor-oil seed chaff, and castor oil, and at other times with poppy-seed cake, which has not half the value of groundnut cake. Some East Indian rape cakes are full of myronates, which when brought in contact with water turn into mustard oil, which may do the cattle harm, and therefore it is obviously necessary to know where the cake comes from. Groundnut cake, when adulterated with poppy-seed cake, has a tendency to go musty, and the opium in the latter is very bad and dangerous for the cattle, while the milk of cows fed with this stuff cannot fail to be injurious to young children. Cakes which have been badly stored sometimes get heated, and this causes the protein to decompose, with the alarming result that the food may not only make the cattle ill, but actually kill them. These cakes have frequently been ground up and mixed with good meal, and then sold for feeding purposes. Such a case of fraud, the consequences of which cannot be estimated or foreseen, is one of the worst that has come to my knowledge, and is, as you will see, a very difficult one to detect and punish. Oilcakes of all kinds are often adulterated with the husks of cereals, which are themselves absolutely without feeding value, and merely load the stomachs of the animals unnecessarily. Then, again, dried grains from breweries and distilleries, malt-sprouts and molasses, and dried beetroot slices, which should, according to Dr. Maereker's table, contain protein from 6 per cent. to 33 per cent. and fat up to 23 per cent., are, however, often adulterated to increase their weight with sand, tale, lime, oxide of iron, and manganese. The weed seeds gathered in the cockle machine, which cleans the grain before it is ground into flour, are sold for the purpose of adulterating feeding stuffs, and these are distinctly injurious and poisonous. They are henbane, spurge, crow's-foot, yellow rattle, ergot, &c., comprising altogether about 72 different varieties.

Kind of the Feeding Stuff.	Protein.	Fat.	Non-nitrogenous Extract Compounds.	Total of Feeding Value Units.	Price.	
					Per Cwt.	Cost per Feeding Unit.

The necessity for microscopical and bacteriological examination of feeding stuffs is of the very greatest importance. As a rule one may form an opinion of the purity or otherwise of a feeding stuff from the appearance of the textures or elements of textures, and it is therefore almost indispensable that chemists should make themselves sufficiently acquainted with the use of the microscope so as to be able to examine and judge the feeding stuffs from a botanical point of view. There are three distinct microscopical methods in use, namely—(1) Witmack's paste method, (2) Bencke's flour proof method, and (3) Dr. Von Weinzierl's mechanical microscopical examination. Special directions as to how to proceed cannot be laid down, but every one must be left to choose his own way. Every sample, however, should first be examined on the outside for animal or vegetable parasites, or foreign admixtures, and if any are detected the sample ought to be put aside to be in due time further examined.

This brings us to the question as to when a feeding stuff may be considered to fall into one of three categories, namely—(1) impure, (2) adulterated, and (3) injurious. By the last-named, of course, I mean injurious to the animals, or to those who use the products, such as milk and butter. Under the first and second heads I would include adulterations which cannot be proved to be injurious, but which have a less nutritious value and are added to make the article cheaper, or for fraudulent reasons. It certainly should be punishable by law to offer as feeding stuffs articles which contain from 30 to 40 per cent. of materials which are not only absolutely valueless for nutrition, but overcharge the stomachs of the animals, and which, through continual use, would counteract the effect of or destroy altogether the gastric juice, and harden the organs of digestion. But before pursuing this question further, permit me to repeat that I fail to see what good would be done by revealing to the purchaser the secret of the manufacturer who combines valuable by-products, or material, either in the composition of fertilisers or feeding stuffs. What would the manufacturers of Pears' soap, who have kept their secret for more than a century, according to their advertisement, say; or what would the more modern "Sunlight" makers of a similar article, be likely to say to a proposal that every package should have legibly printed upon it every detail of the chemical and other ingredients? You see at once, of course, that such a suggestion is repugnant to common sense, and that the suggestion could

not be entertained for a moment as in the remotest degree approaching practicability. This does not apply, of course, to compounds containing simple elements, the proportions of which can and ought to be guaranteed to the purchaser. It only applies in the case of a manufacturer who has made his feeding stuff a specialty by careful and laborious research, and who certainly ought not to be called upon to proclaim the results from the bonetops for the benefit of less industrious rivals. In my opinion—which, of course, I give merely for what it is worth—it ought to be quite sufficient if, in the case of fertilisers, the percentage of nitrogen, potassium, lime, and phosphoric acid was published, and in the case of feeding stuffs that of protein and fat. This would enable the manufacturer who had his wits about him to mix such products as come, for instance from East India and Africa, where, for want of good machinery, the oil is not properly squeezed out of the seeds, or other raw material with their own oilcake and so make a mixture that would be of a better value to the farmer than it would be without this addition. That such mixtures are legitimate has lately been demonstrated in a very able and interesting paper by Professor Maereker, in which he specially dilates on the scientific way of putting such mixtures together so as to secure as much nutriment as is contained in bran, while, taking into account the high price of the latter at the present moment, they would not cost more than about half the price. I will give you here the gist of his calculations. The average figures of the nutritious contents have been taken from the analysis of the fodders during many years at the experimental agricultural station in Halle. To estimate the nutritious value, he adopted the figures of value of Professor König of Münster, who laid it down that the feeding value unit of non-nitrogenous compounds may be taken as one; that of fat as double, say two; and that of protein half as much again as fat, or say three; here, however, I must inform you that Professor Maereker writes me:—

"The relative value of protein to fat and non-nitrogenous substances is calculated by the united agricultural trial stations in Germany, according to the method of the smallest squares from the prices of the most important feeding stuffs, and this calculation is checked every year by the variations in prices." The last calculation made by Professor König gave the proportion as 3:2:1, but since then the nitrogenous fat-containing feeding stuffs have risen in cost so considerably that this proportion is no

longer correct—as Professor Maereker knows privately from Professor König—and in the next calculation, which will soon be published, the proportion will most likely be 3:3:1, so that as a matter of fact fat and protein have become of equal feeding cost. This would, of course, be altered as soon as the feeding stuffs which contain much fat fall in price. On the question of what part in the digestion is done by fat, Dr. Maereker says that for the preservation of heat, fat acts equal to its equivalent of heat, that is, 2.5 of the carbohydrates; but that as a nutritious substance in place of albumen it is only equal to 1.8 to 2 of the carbohydrates. The actual part which fat takes in the digestion has not been proved with certainty, but it is generally assumed that the action is both mechanical and dietetic, that is to say that the intestines work better when they are, as it were, lubricated or oiled. I doubt this, says the Professor, and believe that the feeding stuffs which are rich in fat are so highly valued because they always at the same time contain much protein. As far as the actual nutritious value is concerned the fat can be easily replaced by the equivalents of carbohydrates, though an exception ought of course to be made with fats that have a specially favourable influence on the fat of the milk, like that of the palm kernels.

Taking wheat bran at 6s. 6d. per cwt., he says that it contains 13.7 per cent. raw protein, which in the proportion of three to the whole makes 41.1 units, 2.9 per cent. of fat,

which at two makes 5.8 units, and 57.2 per cent. of non-nitrogenous substance which at one makes 57.2 units. Total 104, feeding value units, for which 6s. 6d. has been paid, and therefore one unit costs in wheat bran $\frac{3}{4}$ d. per feeding value unit. It is after this principle that the table (see preceding page) of the most important feeding stuffs has been put together by Dr. Morgan, and with the help of this table it is easy to find which feeding stuffs are, according to the prices of the day, the cheapest, and which it is best to select in order to make up not only the cheapest, but the most nutritious class of feeding stuff. A glance at the last column shows that wheat and rye bran are the most expensive among the fodders named. The question, therefore, of how to replace them by cheaper mixtures is obviously of the greatest importance.

From this table the actual money value of each unit of the feeding value, according to chemical analysis, can be easily seen. Another important point is, however, how much of the feeding value unit of protein is digestible. Sometimes two feeding stuffs of the same chemical composition will vary greatly in their nutritious value, as the total of the feeding value units in the one is more easily and more thoroughly digestible than in the other.

The following table will give a few figures as to the digestibility of the different kinds in the feeding stuffs, and these figures ought to be taken as the basis for calculating the rations of equal value:—

Kind of the Feeding Stuff.	Total of Digestible Feeding Value Units.	The Cost of One Digestible Feeding Value Unit is	Per Cent. Digestible Compounds.		
			Protein.	Fat.	Non-nitrogenous Soluble Matter.
Molasses.....	84.00	<i>d.</i> 0.36	6.0	..	66.0
Dried beetroot slices out of which sugar has been extracted.	73.80	0.48	5.6	..	57.0
Cotton-seed meal.....	168.50	0.49	42.0	11.4	19.7
Groundnut cake.....	170.70	0.49	44.5	6.3	24.6
Poppy-seed cake.....	129.90	0.58	31.9	8.0	18.2
Sesame cake.....	144.40	0.51	35.7	11.7	14.1
Dried distillers' grains, II. (60 per cent.).....	152.40	0.55	30.4	20.7	19.8
Dried distillers' grains, I. (35 per cent.).....	126.00	0.57	24.0	7.2	39.6
Rapeseed cake.....	111.50	0.64	28.4	7.3	21.7
Malt-sprouts.....	100.80	0.50	20.8	1.0	36.4
Hay at 3s. 6d. per cwt.	61.10	0.65	7.5	..	41.6
Clover hay at 1s. per cwt.	70.00	0.60	10.0	..	40.0
Rice feeding flour.....	96.30	0.68	10.0	10.1	46.1
Dried brewers' grain.....	91.40	0.72	18.1	5.0	27.1
Palm kernel cakes.....	89.20	0.77	13.2	7.7	34.2
Cocoanut cake.....	111.70	0.78	19.2	11.9	30.3
Wheat bran.....	80.50	0.96	10.1	2.2	45.8
Rye bran.....	92.70	0.97	13.5	2.6	47.0

From this table you will see that the braus are by far the most expensive feeding stuffs of all, for in the cotton-seed and groundnut meal a feeding value unit will only cost 0.49d., whereas in wheat and rye bran just twice as much has to be paid for it, that is, 0.96d. and 0.97d. respectively. Molasses and dried beetroot slices, the by products of the beetroot-sugar manufactory, also are much cheaper. This is one more reason—though I must plead guilty to having mentioned it in previous lectures here—to recommend the introduction of the beetroot-sugar industry in England, as it would enable the farmers to get their feeding stuffs in the form of molasses and beetroot slices so much cheaper. A feeding stuff having a nutritious value, both on account of its nitrogenous elements, as well as of those that are free from nitrogen, that is to say, a replacement of one nutritious element

by another of equal value, can, of course, only take place if the different nutritious contents, or compound elements, are in the same proportion to one another. This, however, is very seldom the case, and this is the reason why it is necessary to mix different stuffs, as, for instance, to mix a feeding stuff very rich in nitrogenous matter with a poorer one, and use that in place of a medium nitrogenous fodder. As an illustration I may say that it would not do to replace bran by cotton-seed or groundnut meal, as in these, to every one part of digestible nitrogenous, nutritious substance, there would be only 1.15 non-nitrogenous—that is fat—whereas in wheat bran the proportion is 1 to 1.508. It is, however, possible to make up for this, if to the mixture is added a substance that has a large proportion of non-nitrogenous nutritious matter in comparison with the

nitrogenous contents, as, for instance, rice meal (1:7·1), dried beetroot slices (1:10·2), and molasses (1:11·0). The two latter, which can be obtained in abundance in all beetroot-growing countries, are really some of the most useful and cheapest feeding stuffs, and cannot be too highly recommended to farmers for this purpose.

As to the dietetic influence of bran as one of the most esteemed fodders, I may say that a great many mixtures made up according to the principles already shown have been used with the very best results for years by the greatest cattle rearers on the Continent. Feeding with bran has only been adhered to in the rearing of young animals and with milch cows which are kept for young children.

May I venture to suggest in conclusion that it is evident that the question of feeding stuffs is to the British farmer of the greatest importance, for, in spite of the decrease in agricultural pursuits in this country, cattle and other domestic animals have increased in numbers as the following figures show :—

----	Horses.	Cattle.	Sheep.	Pigs.
1880.....	1,432,620	6,508,632	27,272,450	2,773,609
1891.....	1,488,403	6,852,821	28,732,558	2,888,773
Increase in 1891.	55,783	344,189	1,460,099	115,164

Now, if the rearing of cattle is one of the main sources of income for the farmer, nothing should be left undone that will tend to make that industry a thriving one. Moreover, domestic animals are dependent for their comfort and well-being on man, and it is the duty of all stock rearers to feed their beasts with good sound food, and treat them generally in the enlightened manner which science teaches and common sense dictates as being best for both man and beast. The Government, too, must do its duty and recognise the necessity for regulating the trade in feeding stuffs and fertilisers, and stamping out deleterious compounds and the fraudulent manufacturer of them. The Bill which Mr. Chaplin is going to submit for investigation to a departmental committee will not, I fear, do this. It will harass the makers of feeding stuffs and the manufacturer of manures without benefiting the farmer.

First and foremost, efficient agricultural trial stations and laboratories should be established, scientific farming and feeding should be encouraged by every known means. Farmers should be shown the kinds of food which should be given. They should be taught how to mix the different feeding stuffs so as to provide each animal with the substances best suited to its special requirements of befitting its special work, while the supervision of the feeding should be his constant care.

Finally, if the farmer is to do his duty, he must learn first and foremost the rudiments and principles of scientific feeding, gain an intelligent appreciation of the value of the different feeding stuffs and of what special use the principal well-defined chemical substances are, and then he will be soon able to invest his money for fodder to the very best advantage, and by that time he will require no embourgeois law to protect him from being swindled in his purchases of feeding stuffs and fertilisers.

DISCUSSION.

Mr. TATE said that legislation was required, as there was no doubt that at the present time a great deal of rubbish was sold both for manure and cattle food purposes.

The Bill as it at present stood required very considerable amendment, its provisions being very loose and indefinite. He thought it was unnecessary and undesirable to state definitely of what any particular manure was made up, but the nature and percentage of the constituents considered of special manurial value should be distinctly mentioned. A similar course could be followed with cattle foods, although with these it was desirable to state more definitely the substances from which they were produced, as a feeding

cake for example, made from one kind of seed or substance might have a very different value to another on account of relative conditions for assimilation, although the actual proportions of fat, nitrogenous constituents, &c. were the same. As Dr. Schack-Sommer had well pointed out, not only was it desirable to note the chemical constituents of foods, but also other characteristics, as for instance, their texture, which might be sufficiently coarse or rough and indigestible to do mischief by mechanical irritation in the intestines of animals.

Microscopical examination certainly should supplement the chemical in nearly all cases of cattle food, so as to obtain a clearer insight into the nature of the constituents present. One point Dr. Schack-Sommer had alluded to was of the highest importance, viz., that there should be a stipulation that no element of an injurious character should be present either in manure or food, especially in the latter, and here the provisions for the appointment of analysts in different centres would be useful. The appointment of trained analysts for special agricultural purposes would prove of great service to agriculture generally, providing farmers and others made use of their services. It was quite possible to so amend the present Bill as to make it a really useful measure; and Dr. Schack-Sommer had done good service in calling attention to it so that those interested could think over in what direction amendment might be possible.

Dr. LEATHER said he did not think that the majority of manufacturers practised adulteration, and certainly the larger portion of the materials sold as manures were not adulterated; but he did think at the same time that there were a number of smaller dealers who did habitually adulterate to a large extent. There was an admitted necessity for legislation, but in what way were they to legislate? One of the knottiest questions in the discussion of that measure would be as to the way the materials should be branded, if at all; whether the percentages of ingredients should be branded, or whether a statement should be given that the bags contained merely such and such materials. At first sight it did seem best that the bags should be branded, showing that they contained certain percentages of phosphoric acid, nitrogen, &c. It was not, however, so simple as that, because these ingredients—phosphoric acid, nitrogen, potash, &c. might be derived from different materials in which they were present in forms of varying assimilability. It was not sufficient to say that a manure contained, for instance, so much nitrogen; they must indicate also in what form that nitrogen was present, in order that the farmer might know what its worth was.

With compound manures, the only thing would be for manufacturers to brand percentages if they had to name them at all. Personally, he thought the best plan would be to use simple materials, and not buy compound manures. The quality of the materials of which food stuffs were made was of greater importance than the actual percentage of ingredients contained in them. Mr. Tate had pointed out the absolute necessity for those materials which were offered as food for stock being made of thoroughly sound substances, and he (Dr. Leather) objected there again to recommending farmers to use compound materials. It would be better if the farmer used simple materials and mixed them himself; most farmers possessed machines for crushing, &c.

The only way to make the Bill work at all would be to appoint, not merely chemists, but inspectors also, and that manures and food stuffs should be analysed and sampled by the county authorities whenever they thought fit, making it on a par with the Food and Drugs Act of to-day. If the Bill were passed in its present form and it were left to the farmer's own initiative to employ the chemist, he was persuaded that the provisions of the Bill would be practically inoperative.

Mr. SMETHAM said that Dr. Schack-Sommer had brought a severe indictment against manufacturers generally, and shown that all sorts of things were adulterated to a great extent. It was doubtless true that such adulteration did exist, but not to the extent that the lecturer would have them believe. As the result of considerable experience in analysing both feeding stuffs and manures, he maintained that so far as the large manufacturers were concerned, the

substances sent out were usually what they were represented to be, and of good quality, the adulteration and the misrepresentation being done chiefly by the smaller dealers, who bought a thing in one name and sold it as another, transacting their business usually with the more ignorant farmers over a pint of beer in the public-house. The Bill in its present form was quite unworkable. Manufacturers would never allow such a Bill to pass; manufacturers of food stuffs, such as calf meals, would never state in detail the whole of the constituents. To do so would do away with all enterprise, and many of the best men would leave business—that is if they were compelled to tell their secrets to every rival. Another difficulty in the Bill, which had already been pointed out, was that the working of the Act depended entirely on the voluntary sending of samples by the purchasers. Farmers generally would not take the trouble and pay for the analysis, and manufacturers would object to the district analyst and go to the chief analyst, and by so doing would place obstacles in the way of the successful working of the Act. The Bill in its present form was practically dead, and was to be referred to a Committee, when all points would be thoroughly thrashed out.

Mr. DAVIES pointed out that with regard to the general question, so far as food stuffs were concerned, it would not do for the manufacturer to be obliged to specify all the materials he employed, though it seemed quite practicable that the amount of fats, proteins, &c. should be stated, and that the manufacturers should give a guarantee that no injurious substances were used. Regarding manures, in his experience, manufacturers did supply the article that they claimed to do when analyses were given.

Dr. SCHACK-SOMMER, in reply, said that in his paper he had laid stress on the fact that large consumers would not object to send samples for analysis, but that the small farmers, if they knew of the existence of such a being as an analytical chemist, would shirk the expense of sending samples of their purchases to him, as even the smallest fee would increase the cost of the manures or feeding stuffs. He therefore thought that the advice of consulting chemists paid by Government or county councils should be at the disposal of the small farmers free of charge, as was done with regard to the Food and Drugs Act. Money expended in that way would repay itself a thousandfold. All through his paper he thought he had made it clear that he was particularly anxious to protect the small and generally less educated farmer, the man who really did not know what he ought to buy when he made his purchases of manures and feeding stuffs. He cited a case lately reported in the newspapers, where some unscrupulous person had sold to various farmers in the South at 5*l.* per ton refuse from tanneries for which the tanners hitherto had paid 10*s.* per load for getting rid of, and which had no fertilising value whatever. It should be made compulsory to send samples of all purchases for analysis.

Dr. Leather's point was, that it was more important that manures should have the names of the principal ingredients printed on the bags than the percentage of nitrogen, phosphoric acid, lime, and potassium. In nitrate of soda and sulphate of ammonia the nitrogen was undoubtedly at once available for absorption by the plants when put in the ground; whereas in leather and shoddy, with their small percentage of nitrogen, this was not the case, and he would therefore suggest that only soluble nitrogen should be the basis of the purchase. There should be no possibility that those who desired to buy a certain article, say for instance sulphate of ammonia, should get something else mixed with sulphate of ammonia.

Manchester Section.

Chairman: Ivan Levinstein.

Vice-Chairman: Edw. Schunck.

Committee:

J. Angell.
G. H. Bailey.
R. F. Carpenter.
G. E. Davis.
Harold B. Dixon.
H. Grimshaw.

J. Grossmann.
P. Hart.
A. Liebmann.
Sir H. E. Roscoe, M.P.
C. Truby.
D. Watson.

Hon. Local Secretary:

J. Carter Bell,

Bank House, The Cliff, Higher Broughton, Manchester.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies and will take office in July next:—Committee: F. H. Bowman, J. M. Irving, and E. Kuecht.

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

Meeting held Friday, 6th May 1892.

MR. I. LEVINSTEIN IN THE CHAIR.

TESTING THE ILLUMINATING POWER OF COAL-GAS.

BY GEORGE E. DAVIS, F.I.C., ETC.

A TRIAL of the illuminating power of coal-gas is not in any sense a chemical operation: it is a physical measurement of the result of the combustion of coal-gas in ordinary air measured against sperm candles burning at a specified rate.

It will be known to most of you that a Select Committee is now sitting, having for its object an inquiry into the subject of a standard for photometric purposes, the sperm candle for a long period not having been considered satisfactory. It will therefore be obvious to you that I could not enter into a discussion upon the matter of a standard light, but there are many other points open to consideration, contrasting the basis upon which physical tests are made with that upon which chemical examinations are founded. It may be taken for granted that if coal-gas was always of one and the same quality, there would be no need for a trial to be made of its illuminating power. But coal-gas is not a simple gas, it consists in a great measure of non-illuminating hydrogen and feebly illuminating marsh-gas made luminous by partial saturation with the vapours of benzol, toluol, crotonylene, and other hydrocarbons, the excess of which vapours are found in the tar which is condensed from the crude gas. The gases further do not come off from the coal in regular and even proportions, the composition of the gases given off during the first half of the period of carbonisation yielding greater luminosity than those given off during the latter half. In fact, towards the end of the charge, little else than pure hydrogen is given off, having very little, if any, luminosity when burned.

I am fully aware that the gas leaving the hydraulic main in a well-regulated gasworks is of fairly constant composition—its illuminating power will vary in different works, according to the length of time (and temperature) the gas is allowed to remain in contact with the tar, and this is brought about by the regular and alternate system of charging the retorts; but it is possible that a variation of quality from this source may have to be considered in the future, as it would be quite easy to arrange the charging so that that of 20-candle power could be collected from the anterior portion of the charge, and 10-candle gas from the posterior,

I do not suggest, however, that any irregularity occurs through charging the retorts, except in small and terribly mismanaged works.

The quantity of gas yielded by the ton of coal does, however, affect the illuminating power, as you may learn by studying the paper read before the London Section of this Society in 1884 by Mr. Lewis T. Wright, who was then manager of the gasworks at Nottingham. My own experience in this matter is not a small one. In the gasworks I was instrumental in establishing near Sheffield, it was my aim to secure a large quantity of illuminants, and as the result of many experiments, working the same quality of best fresh-wrought gas-coal, I obtained 9,060 cub. ft. of 18-candle gas to the ton, 10,100 ft. of 16-candle gas, and 11,400 cub. ft. of 14 candle gas to the ton of 20 cwt. In the first case the coke was too soft for sale, in the last case it was hard and saleable. The tendency is nowadays to run the production up to the highest possible limit, and without more benzol is volatilised from the tar than formerly, the result will be a debased gas.

There is another reason why coal-gas should have trials made of its illuminating properties. A process was introduced some years ago, better known perhaps as Hawkins' process, for introducing carburetted air into the gas before its entry into the oxide purifiers, in order to prevent the necessity of so frequently changing the contents. The oxygen of the air introduced acts upon the sulphuretted hydrogen in the presence of oxide of iron, forming water and free sulphur, while the nitrogen remains in the gas, diluting its illuminating power. Now the testing of the illuminating power of coal-gas is not such a simple process as the testing of butter for margarine or of milk for added water. Parliament in its wisdom has seen fit to prescribe that certain forms of apparatus shall be used for trying the illuminating power of coal-gas. I take it that the Legislature has only sought to ensure that reliable methods and apparatus should be used, so as to guarantee that the consumer gets what he pays for, for it is pretty obvious that the producers may as a rule be left to take care of themselves.

Part I. of the schedule of the Gas Works Clauses Act of 1871 specified that "the apparatus for testing the illuminating power of the gas shall consist of the improved form of Bunsen photometer known as Letheby's open 60-inch photometer or Evans' enclosed 100-inch photometer, together with a proper meter, minute clock, governor, pressure gauge, and balance." "The burner to be used for testing the gas shall be such as shall be prescribed." "The candles used for testing the gas shall be sperm candles of six to the pound, and two candles shall be used together."

Such are the regulations in respect of testing apparatus, but strange to say, though the Gas Acts are so stringent with respect to the testing of meters, there are at present no compulsory powers for the public testing of photometers. A photometer may be perfectly accurate when first purchased, but a disarrangement or displacement of the scale, the candle balance, or the standard burner, is quite enough to give the most fallacious results, and there is no compulsory provision for verifying these instruments.

The President of the Eastern Counties Gas Managers' Association, in an address delivered at Sleaford in March last, said: "I maintain that gas men have no business to bother about these developments of the illuminating power of gas. The people who buy and not the people who sell the gas should take this trouble." This is all very well, but as the cost of either of the instruments, duly fitted, prescribed by the Act of 1881, is about one hundred and twenty pounds sterling, it is not likely that many gas consumers will incur the expense.

It will thus be seen, as I have already stated, that the testing of coal-gas is placed on quite a different footing to such substances as butter, milk, &c. In the testing of these substances the Legislature does not step in and say what size filter shall be used, how the alcoholic potash shall be made, or the particular kind of gas-burner employed for heating the flask, and in the many prosecutions which take place on this matter, no counsel ever thinks of questioning the apparatus or methods employed by the expert whose testimony is to convict or acquit the defendant.

This is not the case with coal-gas, the suppliers can legally object to the use of any other apparatus than that specified, but this of course makes no difference whatever in the accuracy of the results. In fact, various details of photometry have been greatly perfected since 1871, and I doubt very much, if a Gas Works Clauses Amendment Act were passed to-morrow, whether the apparatus and methods would be the same as specified in the Act of 1871.

My own photometer was designed not only for the examination of ordinary coal-gas, but for the purpose of all-round uses, one of which was a thorough examination of the illuminating power yielded by the vapours of different hydrocarbons, and of which I hope to speak to you at some future time.

My photometer may be called a 60-inch enclosed "Evans," but it differs from the "Evans" in that the scale is divided into inches and tenths instead of being graduated for "candles." This makes a calculation necessary for each experiment, but as we have calculated a table for each possible position of the screen index, a simple inspection of it gives the candle-power direct. The apparatus is fitted with an experimental meter reading to the one-hundredth of a cubic foot; it is also fitted to burn either the prescribed pair of sperm candles, or a ten-candle Methven light prepared with great care for me by the well-known firm of W. Sugg and Co., the gas to be tested is burned in one of Sugg's London argands as prescribed.

We have now made nearly 1,000 tests with this apparatus, and I have thought that a summary of the results may be interesting to you. As the apparatus was fitted in our laboratory we had to be satisfied with the Salford gas supply, a photometer of this kind not being a very portable instrument. The reason a ten-candle standard was adopted was, first, because it is a very convenient standard having regard to the experiments in which I was engaged, and secondly, because the screen is thus brought nearer the centre of the graduated bar, thus ensuring greater accuracy than when a two-candle standard is employed, and thirdly, there will only be the same absolute error in adjusting a ten-candle standard as in making a two-candle standard, in which latter case the error, if any, is five times greater than with the ten-candle standard. This ten-candle standard was presumably made and standardised with London gas. When tested with Salford gas against sperm candles burning 120 grains of sperm per hour, it yielded a light of 9.94 candles; 30 separate tests were made to establish this, according to the directions given for testing gas by the Gas Referees. Of these 30 tests, five were rejected owing to the abnormal rate of consumption (being below 144 grains or over 126), while if the 10 nearest tests to 120 grains be taken the illuminating power comes out exactly ten candles.

When the testing was first established I was surprised at the low results, and having satisfied myself that the ten-candle standard was correct, absolutely, I carefully examined every point in detail without finding any error. The testing was continued in this manner for about three months, the average value coming out about 15.7 candles. The apparatus was then altered by the substitution of a pair of sperm candles for the ten-candle Methven standard and tests were made twice a day for upwards of three months. The average in this case came out 15.4 candles.

The nuisance of using candles in place of the Methven standard was so obvious in the foregoing experiments that candles were abandoned, and in continuing the experiments the Methven standard was alone employed, and further experience has shown me that it is far more reliable than the sperm candle, and much more convenient to use.

A few words as to the consumption of sperm in nearly a thousand tests may not be out of place, the consumption was most irregular, varying from 108 grs. on the one hand to 137 grs. on the other. The Gas Referees having prescribed that all tests in which less than 114 grs., or more than 126 grains are consumed should be discarded, and this has been done in all our tests; the proportion discarded has been 15 per cent. The tests retained, in which less than 118, or more than 122 grains were burnt, amounted to 55 per cent., while the test burning from 118—122 amounted to the remainder of 30 per cent. This is the boasted parliamentary standard, and to do it as much justice as possible,

I may say that the candles were from a recognised leading maker. It would be invidious to mention his name. My experience in photometry leads me to say most emphatically that the parliamentary "candle" is by no means a *standard* that analytical chemists would be satisfied with, it might suit gas engineers, but not a chemist with any idea of accuracy.

And this leads me to another point. Coal-gas is usually tested at the gasworks, which in my opinion is a most unjust provision of the law. Consumers do not burn the gas at the gasworks, and sometimes there is a great difference between tests made in the gasworks and tests made half a mile away. My own tests are cases in point. Taking the Salford supply to our laboratory, on July 2 last year by my photometer the gas tested (day supply) 13·4 candles; on November 16, 13·2 candles; December 5, 13·6 candles; December 22, 13·1 candles; December 23, 12·3 candles; and December 24, 12·5 candles. The two last tests were made during the very foggy Christmas week when gas was being burned all day long, and when the consumers were complaining to each other very generally that "the gas was very bad." A summary of the whole of my tests of our gas supply from July 1, 1891, to February 27, 1892, is as follows:—

Month.	Illuminating Power.	Grains of Sulphur per 100 Cubic Feet.	Carbonic Acid vols. per Cent.
July 1891	14·70	16·81	0·56
August 1891	14·31	11·60	1·22
September 1891 .	14·40	17·12	1·14
October 1891	15·20	20·01	1·13
November 1891 ..	15·46	21·92	1·05
December 1891 ..	14·72	21·88	0·98
January 1892 ...	15·00	19·07	1·12
February 1892 ..	14·75	19·86	1·07

Now, the results of these examinations do not agree with the tests made at the gasworks, why I do not pretend to explain, but I have convinced myself that the readings of my photometer are accurate; each point has been checked in every possible way, and there is practically no difference in the results obtained with either candles or the Methven standard, provided that all tests be rejected in which an abnormal combustion of sperma has taken place. Again, a 10-candle standard made in London tests exactly 10 candles upon my photometer though used with a different gas. But the Salford gas committee say that the tests made by them (in the works) averaged for 1891, 18·86 candles at one works, and 18·71 candles at another station. This is very poor consolation for those who have to burn the gas a mile away from the works, and I am of opinion that the subject is important enough for the city council to investigate over the heads of the gas committee.

The foregoing remarks bear upon gas-testing generally all over the country, and if this paper falls into the hands of our legislators I hope they will consider whether the time has not arrived when the testing station should be removed from the precincts of the producing works to some public office at a distance. Salford is a good instance: there are the town halls at Salford, Broughton, and Pendleton, each served by the Salford works, why should not a photometer be fitted up in each place, and the borough analyst deputed to make regular tests on each apparatus? Such a process would undoubtedly be more assuring to the consumer than the present system; if the results should turn out identical with those obtained at the works, those in charge of the works would not complain, while if the results differed the sooner the cause of it was discovered and remedied the better for all concerned.

One thing has struck me during these experiments, and that is the ease with which a special standard for each gas supply might be made and verified. It is simple, though somewhat tedious, to make a large number of tests with sperm candles, rejecting, say, all under 118 grains and all

over 122 grains consumption. A Methven screen could thus be cut with very great accuracy, and this could be made of the minimum power the works were allowed to supply. Such a standard should not be put into use before verification by the Standard Department of the Board of Trade, and reverification should be made compulsory every six or 12 months under heavy penalties for disobedience.

At present I am not aware that the verification of photometers is compulsory. I have already pointed out that serious differences have appeared between the results obtained with my photometer and that of the Salford gasworks; may they not be due to the employment of an unverified photometer at the gasworks.

The Gas Act is faulty in many respects, and now that I have given the results of my experience I hope the matter will be taken up, and the testing of coal-gas for its illuminating power be put on a proper basis.

DISCUSSION.

MR. CARTER BELL said he had made some experiments with Mr. Davis' photometer, and was bound to admit that the 10-candle standard as used by him and his method of graduation of the beam was an immense improvement on the ordinary method of testing coal-gas, and he believed far more accurate than the photometer mentioned in the Act of Parliament.

DR. GROSSMAN said that the difference in the illuminating power of gas, as shown by the photometer at the gasworks and by the time it reached the consumers, might be accounted for by the hydrocarbons deposited in the mains; but, in his opinion, the consumers had nothing to do with this, as gas companies and corporations should be compelled by their Act of Parliament to supply gas of a certain standard to all their consumers however far they might be situated from the works.

DR. DREYER thought that, as gas contained certain hydrocarbons which produced the illuminating power, it was a question whether it could not be more accurately tested by chemical analysis than by the ordinary means of photometry.

DR. CARL WEBER said he was afraid that the relation between the hydrocarbons and their illuminating powers was so complicated and exceedingly difficult of interpretation that the photometric test was the best test of the illuminating power of gas, and that chemical analysis was not admissible.

MR. STENHOUSE (of Rochdale) wished to know if Mr. Davis had noticed any considerable difference between tests made in the daytime and those made at night? It was quite possible that they had not been so particular in the daytime when the gas was not used for illuminating purposes. It was generally acknowledged that the best time for making a test was at night time, when the largest consumption was taking place, but Mr. Davis' experiments seem to have been made during the day.

DR. BOWMAN said it was usually considered that a greater condensation took place in the daytime than at night, when the gas was more agitated by the increased consumption going on. He had found as much as five-candle power difference, between noon and night. He was quite convinced from experiments which he had made that the mechanical means of testing was much better than any chemical method could ever hope to be.

MR. WILSON said that when, in consequence of complaints which had been made by consumers at Bury, the gas committee established a photometer some distance from the gasworks. Serious differences were found between the quality of the gas at the gasworks and the testing station, and this difference was at the time attributed to condensation.

DR. BAILEY wished to call attention to a fact which might have been overlooked, and that was that very frequently low results were obtained simply through air having got into the pipes, and the gas not being allowed to burn before the test was made.

MR. GEORGE E. DAVIS, in reply, said, referring to the remarks of Dr. Grossman, he did not consider that condensation in the mains was a serious matter. He had been served with gas some miles away from the gasworks, and it was practically delivered to him at the same degree of illuminating power as it left the works, there not being more than half a candle difference. Besides, if condensation kept taking place in the mains, this condensed liquid should appear in the street syphons, where it is well known that nothing but foul water usually appeared. A deposit of hydrocarbon from the gas could only take place if such gas were saturated with hydrocarbon vapours. He had never yet met with a sample of gas thoroughly saturated, and he quite agreed with Dr. Grossman that gas companies should supply all their consumers with gas of the standard illuminating power. It was not sufficient to test at the works, which he thought had been sufficiently proved. If gas were tested outside the works in some public building from the ordinary mains, he felt quite sure the complaints of bad gas would be reduced to a minimum. In reference to Dr. Dreyfus' remarks, he was of opinion that the physical test of photometry was far more reliable than it was possible to make any chemical test. For instance, there was a great difference in the illuminating power of the vapour of benzene (C_6H_6) and hexyl hydride (C_6H_{14}), while the chemical difference, so far as regarded percentage of hydrogen and carbon, was very small. Dr. Frankland and others had attempted to value the illuminating power of coal-gas by means of its chemical composition, but it was his opinion that all such endeavours must end in failure. In reply to Mr. Stenhouse, the tests of the gas were made in the Manchester technical laboratory at 10 o'clock in the morning and between 3 and 4 in the afternoon, and he did not attribute the difference between the tests made at the gasworks and his own tests to anything more than the presence of nitrogen and air. It was impossible to have gas of a high quality when it contained as much carbonic acid, nitrogen, and oxygen as the gas did in the daytime, and this bore upon the question put by Dr. Bailey. Every precaution was taken to sweep out all the old gas from the pipes before a test of any kind was made, as at 9 o'clock in the laboratory a large gas sand bath was always lighted and kept burning for an hour before a test commenced; and further, the instructions of the Gas Referees as to the testing of gas were always implicitly followed. If the argument were a valid one, that hydrocarbons were deposited in the mains during a slow flow of gas and taken up again in the equal rush by night, the candles lost in the daytime should increase the luminosity of the gas in the evening, but he had never found such an increase, although there was a difference between the day quality and the night quality; but this difference was mainly due to the greater percentage of nitrogen in the daytime than at night.

THE ESTIMATION OF NITROGEN IN COAL-GAS.

BY C. H. NEW.

AMONGST the numerous methods which have been suggested for the estimation of nitrogen, there are, to the best of my belief, none which are not based either upon the conversion of the nitrogen into ammonia, or measuring the volume of gas obtained after the removal of all other gases, by absorption or other suitable means.

Owing to the presence of appreciable quantities of cyanogen and basic compounds, the former method is not capable of being readily applied to the estimation of the nitrogen in coal-gas, and therefore it is upon the latter method, namely, that of ascertaining the volume of the residual gas, that the method which I shall shortly describe is based.

The circumstances which created the need for a speedy and accurate method for the estimation of nitrogen gas, arose in connection with some experiments which were

being conducted by my esteemed principal Mr. G. E. Davis, in the Manchester Technical Laboratory, upon the amount of air which it is advisable to introduce for the purpose of purifying coal-gas.

In order to accomplish this end, Hawkins suggested the use of carburetted air, but during recent years the practice of introducing air pure and simple into coal-gas (previous to its passage through the purifiers) so as to oxidise the sulphur compounds and assist the purifiers to maintain their activity, has rapidly grown in favour amongst gas managers.

Under these conditions it is without doubt advisable to ascertain that air is not introduced in unduly excessive proportions. It is with this object therefore that the following method has been adopted, since by ascertaining the amount of nitrogen present prior to, and subsequent to, the introduction of air, a very close approximation of the amount of air introduced can be made.

The outline of the method consists in first removing the majority of the bases, and certain hydrocarbons such as benzene, xylene, &c., by passing the gas through strong sulphuric acid (sp. gr. 1.85) and then converting the whole of the remaining hydrocarbons into carbon dioxide and water, by passing the gas over red-hot copper oxide. The gases which result from this treatment consist of carbon dioxide and nitrogen, so that the former may be absorbed by caustic soda and the volume of the remaining nitrogen ascertained.

The apparatus employed is not of a very elaborate nature, the idea being that the manipulation should be as simple as is compatible with accuracy. It may be divided into five parts.

- (1.) An apparatus for generating CO_2 .
- (2.) A burette graduated to hold 100 cc. of gas, fitted at the top with a three-way tap, and connected at its lower extremity with an aspirator.
- (3.) A combustion furnace containing a combustion tube about 80 cm. long, projecting some 10–12 cm. beyond the furnace, and packed with coarse copper oxide to within 7 cm. of the ends of the tube which are fitted with india-rubber bungs. Through each bung a piece of small-bore glass tubing passes, one of these being connected with a small bottle of about 30 cc. capacity containing strong sulphuric acid.
- (4.) A receptacle in which to collect the CO_2 and nitrogen resulting from the combustion of the coal-gas, capable of holding 200 cc., and graduated with a containing mark at 150 cc., and at 200 cc.
- (5.) Hempel's gas apparatus.

For the generation of the CO_2 , HCl and marble are used. The familiar arrangement of two aspirating bottles as generally employed for the preparation of hydrogen sulphide gas is preferable to a Kipp's apparatus, as the gas can then be generated under pressure.

It is advisable to about one-third fill the generating flask with broken glass before introducing the marble.

As it is essential that the CO_2 employed should be completely absorbed by caustic soda, HCl and marble have been selected for the generation of this gas, upon the authority of Hufschmidt (Ber. 18, 1441) who states that these reagents are preferable to sodium carbonate and sulphuric acid, three litres of the CO_2 obtained from marble and HCl containing on an average 0.2 cc. of gas unabsorbed by caustic soda.

The gas burette may conveniently be made from an ordinary 100 cc. tube fitted at the top with a good india-rubber bung, through which passes, flush with the bottom of the bung, a well-greased three-way tap. (In a case of emergency a plain tap connected with a T-tube may be substituted.) The bottom of the burette which is contracted, is connected by thick walled india-rubber tubing with a small aspirator, the burette being firmly held in a strictly perpendicular position by means of a screw clamp attached to a retort stand weighted with lead.

Of the combustion tube, &c. there is no need to speak, the usual precautions in packing the tube being observed.

The receiver which is recommended is shown in the accompanying illustration. It is an Orsat's absorption tube, such as is used for absorbing O by Cu gauze and $AmHO$,

which is easily adapted for this purpose, all that is necessary being to insert a piece of glass tubing of narrow bore into the wide-mouthed tubulure by means of a collar of india-rubber, and to fit the the smaller tubulure at the bottom

with a tap in the same way. The side furnished at the top with a capillary tube is then graduated at the 150 cc. and 200 cc. containing mark, and fitted with a piece of india-rubber tube and a pinch cock.

The Hempel gas apparatus required is similar to that usually employed, two absorption pipettes being requisite, one charged with caustic soda of about (1.30 sp. gr.), and the other with alkaline pyrogallate.

With regard to the fluid over which the gases may be collected both before and after the combustion, mercury of course is to be preferred, but owing to the cost entailed by the loss of this material through careless handling, any other suitable fluid may be employed, as for instance air-free water, or heavy petroleum oil.

The former of the two latter is obtained by boiling distilled water briskly for about 30 minutes after it has attained a temperature of 100° C., and allowing the same to cool in an atmosphere of coal-gas, and will be found perhaps the most desirable substitute for mercury.

The process itself which I am now about to describe, although possibly appearing rather involved when detailed at length, is in practice by no means so, since the whole operation from the passing of the CO_2 to the final reading of the nitrogen may be accomplished in a period of 30 minutes duration.

Assuming therefore that the combustion tube and the copper oxide contained therein have been raised to a full red heat, during which operation a current of air has been aspirated through the tube by means of a Bunsen pump, so as to carry away any aqueous vapour which may be given off, and to ensure that none of the copper remains unoxidised, the air pump is stopped and the CO_2 generating apparatus connected through the three-way tap with the combustion apparatus.

A brisk current of CO_2 is then passed through the sulphuric acid absorber and combustion tube, thus sweeping out all traces of air. After this has gone on for about three minutes the tube connecting the three-way tap with the absorbing bottle is closed by a pinch cock, and the gas receiver having been completely filled with mercury is connected with the other end of the combustion tube taking care to avoid the entrance of any air. The pinch cock intervening between the CO_2 generator and the three-way tap is also closed.

The india-rubber tube connecting the absorption bottle with the three-way cock is then temporarily removed, and after displacing all air in the burette with mercury, coal-gas is admitted by connecting with the gas supply and lowering the aspirator bottle, the gas being adjusted to the 100 cc. mark by levelling the height of the mercury.

The absorption bottle is now again connected with the three-way tap, and the pinch cocks both here and at the top of the receiver opened. The gas is then slowly chased over from the burette through the absorption bottle and

the combustion tube, the rate at which the gas is passing being ascertained by observing the bubbles in the absorber. The displacement of the 100 cc. of coal-gas should occupy about 15 minutes.

When this is done the connexion with the burette is closed and the tap once more connected with the CO_2 generator, from which a current of CO_2 gas is slowly passed through the whole apparatus, displacing the coal-gas in the absorber, and carrying over all the nitrogen in the combustion tube into the receiver.

The mercury in the receiver is brought during the experiment nearly to a level maintaining the gas, however, under a slight pressure, and adjusting the same by means of the small tap at the bottom, so that when the gas reaches the 150 cc. mark, and the pinch cock at the top and the tap at the bottom are simultaneously closed, the levels of the two columns of mercury are coincident with each other. The receiver is then disconnected, and the combustion tube having been opened to the air the pump is again started to reoxidise the copper oxide.

The wide-mouthed limb of the receiver is then filled with mercury and 100 cc. of the gas passed into the Hempel burette. The CO_2 being absorbed with caustic soda in the usual way. It has also been found necessary to remove traces of oxygen from the gas before taking the final reading as nitrogen.

The average amount of oxygen in coal-gas as taken from 19 experiments upon the gas of towns in all parts of the United Kingdom, is, according to Frankland, about 0.3 per cent., and a varying amount of this oxygen passes over the nitrogen and carbon dioxide, though it would be supposed that a considerable portion would be retained in order to reoxidise the reduced copper. Having, therefore, removed all oxygen the volume of remaining gas is noted, calculated on to 150 cc., and after correction for temperature and pressure gives the per cent. per volume direct.

In summarising the foregoing there are five precautions which it is advisable to observe, viz., (1) to work the apparatus under a slight pressure; (2) to make sure that all air is displaced from the apparatus before commencing the experiment; (3) also to ascertain that the CO_2 used is wholly absorbed by caustic soda; (4) to thoroughly reoxidise the CuO so as to avoid the presence of any metallic copper in the tube; (5) and, lastly, to pass the coal-gas at a rate that will ensure complete oxidation.

The figures which are given below indicate the amount of nitrogen found in the Salford gas as supplied to the Manchester Technical Laboratory, being a series of tests made at different times during a period of several weeks.

TABLE I.—SALFORD GAS.

No. of Experiment.	Nitrogen per Cent. per Volume.
1	14.1
2	13.5
3	13.8
4	8.7
5	7.4
6	6.4
7	10.9
8	11.7
9	10.3
10	6.3
11	7.0
12	7.3
13	7.6
14	7.8
15	4.6

In the early days of the gas industry it was considered highly detrimental to the quality of the gas to admit the slightest quantity of air. This belief existed as late as 1878, when in a report made by the manager of the Salford Gas Works it is stated, "To pump air into gas would not simply dilute it . . . but the gas would be absolutely destroyed as regards fitness for lighting purposes, as may be seen by consulting the following table":—

Percentage of Air added.	Illuminating Power in Candles.
Original gas	25.00
2	22.25
5	10.75

It is therefore safe to assume that the amount of nitrogen found in Manchester gas, as given in Roscoe's translation of Bunsen's Gasometry, may be taken as representing the amount of nitrogen existing in the coal-gas itself, and not due to the introduction of air, the amount there stated to be present being 2.46 per cent. Subjoined are two analyses which apparently are drawn from the same source. No. 1 is to be found as an analysis of Manchester gas due to Bunsen, and is taken from Humphrey's "Chemistry of Illuminating Gas." No. 2 is the original as it occurs in Bunsen's Gasometry. No. 2, being in all probability the correct one, is recommended as the more suitable of the two for the purposes of comparison.

TABLE II.—ANALYSES OF MANCHESTER GAS.

	No. 1.	No. 2.
Hydrogen	45.58	45.58
Marsh-gas	34.30	34.30
Illuminants { Etlal. } { Ditetyl. }	6.46	{ 4.08 2.38
Carbonic oxide	6.64	6.64
H ₂ S	0.29
Nitrogen	3.67	2.46
Carbonic acid	3.67
Oxygen	2.46	Nil.

It is noticeable that the amount of nitrogen occurring in coal-gas was in many cases much greater in 1883 and 1884 when the use of air was increasing, as is shown in the following analyses made by Frankland about that time:—

	Per Cent. N
Liverpool	6.10
Birmingham	10.10
Bristol	5.11
London Chartered Co.	5.95
Newcastle-under-Lyme	6.22
Ipswich	10.84
Preston	4.79

There is also another point of interest, which is shown in the following table, which gives the percentage of nitrogen found on different days at varying times.

TABLE III.

Time P.M.	12.30	1.0	1.30	4.20	4.30	7.30
Per cent. per vol. N.	11.7	10.9	..	8.7	..
" "	13.8
" "	14.1
" "	10.3

Time P.M.	8.0	8.20	8.50	9.20	9.40
Per cent. per vol. N.
" "	4.6
" "	7.6	7.8
" "	7.0	7.3	..

It will be seen that the amount of nitrogen occurring in the gas is much larger in the daytime than at night, an occurrence of such significance that it needs no explanation.

DISCUSSION.

The CHAIRMAN asked whether he fully understood the author to say that there was more air in the daytime than in the evening, and how did the air get into the pipes? If it were pumped in, how did he know there was more in the house than at the station? He understood it was due to the distance.

Mr. STENHOUSE thought that the results obtained by Mr. New were most extraordinary, inasmuch as 14 per cent. of nitrogen meant a great quantity of air, which must have been purposely forced into the gas; and not only would there have to be a large quantity of air pumped in, but there would have to be a corresponding proportion of oxygen. Probably the oxygen would be reduced 1 per cent. assuming the coal-gas to contain 1,000 grains to the 100 cubic feet of sulphuretted hydrogen. There would be sufficient oxygen to oxidise the sulphuretted hydrogen and deposit all the sulphur. Therefore a quantity of air would go forward. Was it quite certain that all the compounds that should be absorbed by the sulphuric acid were absorbed by simple bubbling? Surely the gas had to be agitated with the different reagents before the compounds were absorbed.

Dr. GROSSMAN asked if the author had made an analysis of the air, and if so, what figures he had obtained for nitrogen? The apparatus seemed to require to be handled very carefully, or the results would not be reliable to 1 or 2 per cent.

Mr. STENHOUSE stated that, according to a recently published analysis of the London gas, the average was 0.15 per cent. by volume of oxygen and less than 1 per cent. of nitrogen, and this was greatly different from the results shown.

In reply to Mr. Stenhouse, Mr. NEW said that Frankland found on more than one occasion 10 per cent. of nitrogen, and he had himself found oxygen in the coal-gas to an extent which would correspond to the excess left after that required for reducing the sulphuretted hydrogen had been used up. In regard to the complete removal of the compound absorbed by sulphuric acid, sulphuric acid was only used in a bubbling bottle in order to ascertain the rate at which the coal-gas was passing. As a result some of the hydrocarbons were absorbed, but it was immaterial whether they were or not, since they would all be decomposed during their passage over the red-hot copper oxide.

A VISCOMETER FOR TESTING THE VISCOSITY OF OILS.

BY GEORGE H. HURST, F.C.S.

I bring before you this evening a new form of viscometer or viscosimeter for testing the viscosity of oils. No new principle is involved in the construction of this instrument, as you see. It follows the lines on which most of those now in use, and which have been found to give the most satisfactory results are constructed, viz., the determination of the speed of flow of a measured quantity of oil. The instrument differs from those hitherto made in that it requires a smaller quantity of oil, in the oil flowing through a tube of small bore, and in the mode of heating. As you see, it consists of an outer vessel which holds the water required to heat the inner oil chamber. This water is heated by a separate boiler working on the circulatory system placed at one side of the apparatus. I may say in passing that I have found this mode of heating very satisfactory, and in passing I may remark that it would be worth while adopting it in all cases where it is required to heat and keep at a high temperature water-baths and water-jackets, especially where it is not possible to apply a Bunsen burner direct to the water-jacket.

The inner vessel is the oil vessel. From the bottom of this passes a short tube with a narrow bore, the entrance to which is closed by a valve. By raising or lowering of this valve the oil may be allowed to run or be stopped as may be required. A gauge pin to regulate the amount of oil placed in the oil chamber, with arrangements to support thermometers in the oil and the water-jacket, complete the apparatus.

The instrument is not put forward as a standard instrument, but readings of several such apparatus have been found to give concordant results, so that it might fairly be quoted as a standard. At all events, any instruments sent out will be so made as give concordant readings.

The apparatus is an inexpensive one, and possesses many advantages over the viscometers which are in general use by oil dealers.

The following table embodies some readings made with the new instrument, which will serve to show its range and capacity:—

TABLE OF VISCOSITIES OF OILS.

	Temperature—Fahrenheit.

Yorkshire Section.

Chairman: Sir James Kitson, Bart.

Vice-Chairman: Dr. F. H. Bowman.

Committee:

A. H. Allen.	J. Lewkowitsch.
W. B. Brett.	G. Rawson.
T. Fairley.	Jas. Sharp.
A. Hess.	A. Smithells.
R. Holliday.	G. Ward.
J. J. Hummel.	T. Whitaker.

Hon. Local Secretary:

H. R. Procter, Yorkshire College, Leeds.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies and will take office in July next: *Committee*: J. B. Cohen, F. W. Richardson, G. W. Slatter, and J. B. Wilkinson.

Notices of Papers and Communications should be addressed to the Hon. Local Secretary.

Meeting held Monday, 4th April 1892.

MR. GEORGE WARD IN THE CHAIR.

ON THE IMPURITIES IN COAL-GAS.

BY T. FAIRLEY, F.R.S.E., F.I.C.

IN 1886 (this Journal, 283—6) I read a short paper before the Manchester Section on this subject, and I now, at the request of the secretary, bring before you this short note reporting further experience of the method for analysis of coal-gas proposed in that paper.

The chief impurities in coal-gas, itself a complex mixture, are those substances which give unwholesome combustion products, or which interfere with the development of the light-giving properties of the gas when the latter is burnt in an ordinary gas-burner. The sulphur compounds, hydrogen sulphide, carbon disulphide, and other more complex compounds such as thiophene, are among the first, and carbon dioxide, ammonia, air, and nitrogen are among the second.

Of the sulphur compounds, hydrogen sulphide is scarcely ever present in the gas from any ordinary well-conducted works. The processes for its removal are so effective that there is no excuse for the presence of this impurity. Sometimes, in spite of efficient purification, this substance is found in the gas in certain parts of the area supplied, and in two cases within my own experience the source of the impurity was traced to leakage from crude gas-liquor mains, or storage tanks.

Sulphide of carbon and other compounds of a more or less acid nature are generally found in coal-gas supplied to consumers. Their partial removal is effected by means of alkaline earth sulphides, such as calcium sulphide or sulphhydrate. No sulphur compounds of a basic character have as yet been detected in coal-gas.

In my former paper I gave a *résumé* of the methods hitherto used for the estimation of the sulphur in coal-gas as supplied to consumers, and I have before you the Referees' apparatus, now generally used for this purpose (this Journal, 1886, 283).

In place of the solid ammonium carbonate round the burner in the Referees' apparatus, I proposed the use of a dilute solution of hydrogen dioxide, run in through a capillary tube at the rate of about 3 cc. per hour at the top of the condenser. The sulphur dioxide is completely oxidised into sulphuric acid, and may be determined by titration with standard alkali. If a solution of sodium hydrate used contain 0.25 grain NaHO or 0.0162 grm. NaHO per cubic centimetre, then the number of cubic centimetres of standard sodium hydrate give without calculation the number of grains of sulphur per 100 cubic feet of gas, when ten cubic feet of gas are burnt. There should always be a slight excess of hydrogen dioxide in the condensed liquid, so as to secure complete oxidation of the sulphur. I do not advise the use of standard ammonia in this titration, as higher results are obtained when this alkali is used, the dioxide apparently tending to assume the part of an acid. If such an excess of dioxide is present as to interfere with the use of litmus or other indicator, then the liquid may be evaporated to dryness in a small bulk with an excess of standard soda, and the excess of alkali titrated with standard acid.

The dioxide must be carefully tested for impurities, especially sulphuric acid or barium salts.

The gas before burning should be as completely freed as possible from ammonia, by passing through a saturator containing a large excess of sulphuric acid. Minute quantities of nitric acid are sometimes found in the condensed liquid, probably formed by the oxidation of ammonia or other nitrogen compound left in the gas. I have not found this circumstance to practically interfere with the use of the process.

As compared with the ammonium carbonate process, the use of hydrogen dioxide has two other advantages. The reagent is supplied at a uniform rate throughout the experiment,

whereas with ammonium carbonate there is a large excess of ammonia at the beginning of an experiment, followed by a possible deficiency before the twenty hours (required for a ten cubic feet combustion) have expired. There are no solid products, such as ammonium sulphate, formed in the chimney or condenser. The apparatus may therefore be used continually for days together, and a true average of the sulphur contained in the gas supplied at all times obtained by simply analysing a fractional part of the condensed liquid, without washing out the apparatus. This is specially valuable in a gasworks, where it is desired to constantly test the gas as it is made. Under ordinary circumstances a continuous test of the gas as supplied to consumers would give an undue preponderance to the gas supplied during the day, as the sampling would be taken from a smaller consumption.

The numbers obtained by the use of hydrogen dioxide generally give from one to two grains of sulphur per 100 cubic feet of gas more than is obtained by the use of ammonium carbonate. Out of a large number of tests, the following may be quoted:—

Ammonium Carbonate by precipitation with BaCl ₂ .	Hydrogen Dioxide by precipitation with BaCl ₂ or by titration as above.
13.40	{ 15.73 by precipitation. 15.42 by titration.
13.30	15.43 by titration.
13.27	14.71 by precipitation.
12.89	14.60 by precipitation.
12.31	14.31 by precipitation.

I have also devised an apparatus for the continuous testing of gas for carbon dioxide and ammonia, which I have before you. The results obtained by the use of this apparatus I hope to bring to the notice of the Section on a future occasion.

My best thanks are due to my friend and assistant M. B. A. Burrell, F.I.C., a member of our Society, for carrying out many of the tests mentioned in this paper.

DISCUSSION.

The CHAIRMAN inquired whether he rightly understood Mr. Fairley that the "Referees' process" for estimating sulphur in coal-gas only estimated half the sulphur present? Also whether Mr. Fairley had ascertained in his process any of the atmospheric nitrogen was oxidised into nitric or nitrous acids by the hydrogen peroxide employed. It would be very convenient if the sulphuric acid produced could be estimated by the specific gravity of the solution.

Mr. F. W. RICHARDSON wished to know whether the equation, $\text{SO}_2 + \text{H}_2\text{O}_2 = \text{H}_2\text{SO}_4$ was really the result of observation, or whether it was not more likely that the hydric peroxide acted simply as an oxidising agent, parting with its oxygen, and being reduced to water. He also inquired whether it was better in Pettenkofer's process to employ standard oxalic or hydrochloric acid.

Dr. LEWKOWITSCH said that in some experiments he had occasion to make on crude German petroleum, the bad qualities of which were ascribed to sulphur, he first used a process in which the petroleum was burned, and the sulphur was oxidised in the wet way by a solution of bromine in hydrochloric acid, but afterwards adopted a method proposed by Victor Meyer for the determination of sulphur in thiophene; as Mr. Fairley wanted to put a convenient method in the hands of gas managers, was it perhaps possible so to regulate the combustion of the sulphur that the whole might be burnt into sulphur dioxide, and estimated by its action on iodine solution?

Prof. TILDEN said it was interesting to see how faithfully Mr. Fairley stuck to his favourite reagent, hydrogen peroxide. There was a very great advantage in being able to use titration in place of the usual gravimetric method. As regarded the possibility of so burning sulphur that sulphur dioxide only should be produced, a proportion of sulphuric acid always resulted when sulphur was burnt in presence of water vapour. Its production was shown in a very striking way by the drops of oil of vitriol, which often condensed on glass bells suspended over gas burners. In evaporating water in a basin covered with filter-paper over an ordinary Bunsen burner, it was often found that the surface of the paper was charred, not with the heat, but by the action of the sulphuric acid evolved.

Mr. ARCHBUTT suggested the use of phenolphthalein in titration of the CO_2 absorbed by sodic hydrate.

Mr. S. C. LUTON had made a few experiments in the early days of the "Referees' process" under the direction of Mr. Harcourt, with the object of obtaining a more simple method. Attempts to oxidise the sulphur in the gas in the wet way by passing it through a hot acid solution of potassium dichromate or chlorate contained in a Brodie's tube, failed from the liability of the liquid to project from the tube.

The converse method of reduction proposed by Mr. Harcourt (B. A. Reports, 1875) promised much better results. If gas free from hydrogen sulphide be passed through a red-hot tube packed with broken porcelain, a fairly regular proportion, though possibly not the whole of the sulphur, is converted into hydrogen sulphide. This may be absorbed by an alkaline solution of lead nearly saturated with sugar, which retards the formation of a precipitate, and estimated colorimetrically.

Mr. H. R. PROCTER inquired if Mr. Archbutt found phenolphthalein a satisfactory indicator for carbonic acid. In his experience the bicarbonate and not the normal carbonate of soda was neutral to it, and the end reaction was not extremely sharp. He alluded to the injurious action of the sulphuric acid produced by the combustion of gas upon leather, and mentioned a case in which he actually found upwards of $1\frac{1}{2}$ per cent of free sulphuric acid in leather, which had been destroyed in this way.

Mr. ARCHBUTT replied that it was correct that the acid carbonate and not the normal was neutral to phenolphthalein, but that he found the estimation of carbonic acid in water was very satisfactorily accomplished by the use of a standard solution of sodic carbonate with this indicator, the reaction being exact though not very rapid.

Mr. FAIRLEY in reply, said, that the sulphur converted into sulphuric acid by the combustion of sulphur in an ordinary or Bunsen gas-burner varied from one-half to one-tenth of the total, but the product was always a mixture of sulphurous and sulphuric acids.

Specific gravity could not be used in place of titration, to determine the amount of sulphuric acid produced, since the variation due to the acid was small compared with that caused by changes of temperature. The temperature of the air had also some influence on the amount of water condensed with the acid.

Oxides of nitrogen were found in the products of combustion of the gas, but might be due to the presence of traces of ammonia, which purification had failed to remove.

Obituary.

PROFESSOR AUGUST WILHELM HOFMANN, PH.D., F.R.S., &c.

MEMBER OF THE SOCIETY OF CHEMICAL INDUSTRY.

It will remain a disputed question whether in the fields of chemical investigation and research, or in the capacity of teacher of his science and lecturer, Hofmann held most potent sway. But whether considered as thinker, investigator, or teacher, the world has indeed lost a master-mind, and of this fact, England, mindful of his devoted services and brilliant career from 1848 to 1864 at the Royal College of Chemistry, London, will cordially join with Germany, also mindful of a like career at Bonn and Berlin, from 1865 to the date of his decease, in bearing honourable and grateful testimony.

Some of the most eminent English chemists were trained under Hofmann in the Royal College of Chemistry, and one and all retain a grateful recollection alike of the patience and perseverance characteristic of him as a teacher, as of his kindly interest in their progress. Judging from the subsequent careers of so many of his old pupils, it is probably safe to venture the deduction that Hofmann had a clear and accurate estimate of the true position and value of chemical technology as a composite branch of science in itself. The correctness of this deduction receives immediate support when we remember Hofmann's celebrated Report of the Advance and Position of Applied Chemistry at the period of the Great Exhibition of 1851, a report without which, for many years, no chemical library was thought complete, a report still sought after and prized. It is with pleasure, moreover, that the writer records the fact that from the very foundation of the Society of Chemical Industry, the name of A. W. Hofmann has been recorded in our list of members, indeed the very first name of a chemist of distinction mentioned in the very first paragraph of the "Report of Council," which opens this Journal, as that of a distinguished foreigner "who had already expressed a desire to be enrolled upon the register," was the name of Professor Hofmann.

Hofmann was born at Giessen on April 8, 1818, and after first studying modern languages devoted himself to chemistry, under Liebig, at the university of his native town. After graduating, he acted as Liebig's assistant until 1845, and during that time began to devote special attention to the investigation of the coal-tar bases. From 1845 to 1848 Hofmann acted as Privat-doцент in Bonn, whence he removed to London, where he had been appointed superintendent at the Royal College of Chemistry in Oxford Street, now the chemical department of the School of Mines, at Liebig's recommendation, and at the nomination of H.R.H. the late Prince Albert. Among those who attended Hofmann's lectures in Germany were Prince William of Prussia, afterwards William I., German Emperor, and his son, the late Emperor Frederick. Until close upon his death the old Emperor William was kept constantly informed of the progress of chemical science by Professor Hofmann, and one of the first acts of the late Emperor Frederick upon ascending the throne was to confer a patent of nobility upon his former teacher, with whom he was upon terms of close personal friendship. Professor Hofmann remained in London until 1863. The Prussian Government asked Hofmann to undertake the reorganisation of the chemical laboratory at Bonn University, and in 1863 he was appointed Professor of Chemistry in Berlin, a position which he has held ever since; indeed, his last lecture was given on the morning of his death. Hofmann was a great friend of Italy; his vacations were mostly spent in that country, and he was on terms of close friendship with many prominent Italian statesmen, authors, and scientists. Hofmann's doctor-jubilee was celebrated with great pomp last year in German University and chemical industrial circles. To him was due the discovery of the composition of rosaniline, and his researches on this and allied compounds proved subsequently of great technical importance in the Coal-tar

colour industry. His studies were principally in the domain of the organic bases, and he did a huge amount of work on this subject. One of the earlier and once greatly admired aniline dyes, "*Hofmann Violet*," was named after him. In 1868, Hofmann founded the German Chemical Society, of which he was the first president. He was also its president at the time of his death. He was one of the foremost scientific advisers of the German Government.

In 1851 he was elected a Fellow of the Royal Society, and in 1854 received the Royal Medal in especial consideration of his "Researches on the Molecular Constitution of the Organic Bases." In 1875 Hofmann further received the Copley Medal—the highest distinction that science in this country can confer. He has been President of the Chemical Society of London, and was up to the period of his death one of its vice-presidents. The immediate cause of death, which took place on the 5th instant, was paralysis of the lungs. He has gone to his grave laden with distinctions, honour, goodwill, and high esteem.—W. S.

GEORGE HOGARTH MAKINS.

MEMBER OF THE SOCIETY OF CHEMICAL INDUSTRY.

GEORGE HOGARTH MAKINS was born in 1815. He was educated for the medical profession, and passed the usual qualifying examinations, but he never practised. His tastes were from the first strongly directed towards chemistry, which he had the advantage of studying under Professor Daniell, of King's College. After qualifying as a medical practitioner he was successively lecturer on chemistry at the Aldersgate and at the Middlesex Schools of Medicine. For a few years, 1849—52, he carried on the manufacture of pure chemicals at Surbiton, and during this time prepared, by a process of his own, a considerable amount of spongy gold for the use of dentists. At the recommendation of Mr. Field, assayer to the Mint, he then came to London, and after a preliminary study in the Mint laboratory, opened an assay office in Coleman Street. This work proved a great success; he was soon appointed assayer to the Bank of England and afterwards made their referee. Mr. Makins introduced a number of improvements into the process of assaying. He designed a new balance, which was described at the Chemical Society in 1852; he gave up the use of "trial plates" and substituted for them pure gold and silver; he improved the apparatus employed for "acid parting;" he abolished the charcoal furnace and substituted anthracite as the fuel. In 1863 Mr. Makins was obliged by ill-health to retire from the assay laboratory. He continued to deliver a short annual course of lectures on metallurgy at the Dental Hospital in Leicester Square from 1860 to 1880. These lectures were enlarged and published as a "*Manual of Metallurgy*" in 1862; a second edition, much increased in size, was brought out in 1873. Mr. Makins was elected a Fellow of the Chemical Society in 1845, and served repeatedly on the Council. He was an original Fellow of the Institute of Chemistry, and was a member of the Council at the time of his death. He was also an original member of the Society of Chemical Industry. Chemistry, however, by no means absorbed the whole of Mr. Makins' energy; he was an amateur architect of considerable experience, and a thorough musician. He was devoted to the organ, and constructed himself three organs in the course of his life. In his later years a new sphere of activity was opened to him. In 1880 he was elected on to the Court of Assistants of the Society of Apothecaries, and for 12 years was most assiduous in his endeavours to promote the welfare of the Society. He became Master of the Society in 1889. Mr. Makins retained his activity till a few months before his death, which took place on 12th April 1892. Mr. Makins was much esteemed by those who knew him. He was methodical and painstaking in his work, and of a very kindly disposition.

PATENTS.

A Process for Treating Chemically Softened Water, so as to prevent the Formation of an Adherent Deposit in the Feed Apparatus of Steam Boilers. L. Archbutt and R. M. Deeley, Derby. Eng. Pat. 3051, February 19, 1891.

In order to convert any carbonates which may be present in water already softened by the addition of lime, sodium carbonate, &c., into bicarbonate, the gases from the chimney or other source which contain considerable quantities of carbonic anhydride, are brought into contact with the softened water in the softening tank, and before the water enters the injectors or pumps. In one arrangement the water passes from the storage tank by means of a siphon, which rises several feet above the water level. At the top of the bend of the siphon a small pipe is attached, and through this the gas containing the carbonic anhydride is allowed to pass, and is thus brought into intimate contact with the water. In another arrangement suitable for a large plant, the gases from a coke stove are pumped into the water by a special cylinder. A slight excess of carbonic anhydride over and above that required to convert the carbonate into bicarbonate is recommended, the following test being made: 10 cc. of the uncarbonated softened water are treated with the carbonated softened water, until phenolphthalein is decolourised, and from 90 to 100 cc. should be required.—J. W. L.

Improvements in Filters. R. W. Barker, London. From H. Goodacre, Lexington, U.S.A. Eng. Pat. 4817, March 18, 1891.

The improved filter consists of an upright cylinder, with double walls, packed with a non-conducting substance. It is provided with a cover fitting air-tight, provided with a threaded nipple to which may be connected the pipe from the source of supply. The draw-off cock is at the lower end, and above it is a box carrying a removable ice-drawer.

* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

The filter comprises an upper and lower circular disc, both of which have a central hole. The upper disc is provided with several concentric series of curved slots, and with curved depending flanges on the under surface. The lower disc is similarly provided with curved slots, but with the flanges on the upper side. Between the two discs is placed a series of porous filtering cylinders, graduated to fit one within the other, and dividing the filter into a series of annular filtering compartments, a bolt keeping the discs and cylinders in position. The unfiltered water passes through the slots in the upper disc at the upper end of each alternate compartment, through the filtering cylinders to the slots and compartments of the lower disc, and the filtered water is thoroughly cooled before being drawn off, by flowing round the ice-box.—E. S.

Improvements in Digesting Apparatus. W. H. Munns, London. From G. Kaffenberger, Cleveland, U.S.A. Eng. Pat. 6057, April 8, 1891.

The object of the present invention is to produce a digesting apparatus, in which the process may be carried on in a continuous manner. The invention comprises a conduit, which has a receiving and a discharge end. Two valves are arranged near the discharge end forming a chamber in the conduit between the valves. A similar arrangement is provided at the receiving end. Suitable horizontal cylinders, with piston and valves, open at one end into each of the above-mentioned chambers. The digester thus consists of three chambers. For details of the mode of working, which here specially refers to the digestion of straw for paper-making, the specification should be consulted.—E. S.

A New or Improved Filter Pump. F. C. Nordmeyer, Breslau, Germany. Eng. Pat. 7155, April 25, 1891.

The patentee provides a filter in the shape of a pump, which he calls a "filter pump," in which the piston or ram

IMPROVED FILTER PUMP.

is composed of filtering material through which the water passes in a filtered state as the ram is pressed home; the unfiltered water enters the pump through a suction-valve. The accompanying cut shows one of the two modifications illustrated in the drawings.

a is the pump cylinder, *b* the suction-valve casing, with the opening *c*, the ball-valve *i*, and the strainer *d*. To the ram *f* is secured, in a central position, the filtering material *h*, through which the water passes reaching the spout and handle *k* through the stem *g*. An outlet valve is stated to be unnecessary, owing to the resistance offered to the water by the filtering substance on the return stroke.

This pump is intended to replace the ordinary portable pocket filter. It raises the water to a convenient height for drinking and can be readily taken to pieces for cleaning purposes.—B.

Improvements in Apparatus for Ejecting or Withdrawing Vapours and Gases from Pipes and Chambers. E. Edwards, London. From L. Kohrmann, Krauschwitz, Germany. Eng. Pat. 7579, May 1, 1891.

This patent refers to details of manufacture of a porcelain or clay tube provided with an annular opening at one end through which steam is to be ejected for the purpose of withdrawing gases of a corrosive nature from pipes or receptacles. For further particulars the specifications should be consulted.—B.

Improvements in and Relating to Evaporators and Feed-Water Heaters. L. Burnet, Govan. Eng. Pat. 22,863, December 31, 1891.

THE improvements described relate to evaporating vessels specially suitable for supplying auxiliary feed-water to steam boilers, is best shown in connexion with one of the illustrations accompanying the specification, which is here reproduced.

The outer shell 1 is fitted with a cover 2 and bottom 3, secured by angle-iron rings 4 and 5. The heating surface is formed by vertical tubes 6 fitted into plates 7 and 8, and a return pipe 9 for facilitating circulation is fitted to the outside of the shell. The feed inlet valve may be fitted to this pipe at the point 10, 11 is the inlet for the steam, 12 the air outlet, and 13 that for condensed water. The baffle plate 14 is to prevent priming from the surface of the evaporating liquid, and the resulting vapour is carried away through 15, 16, and 17, a safety-valve being represented at 18. The specification refers to several variations, including some with removable tubes. If the apparatus is arranged for use in "multiple effect" the last evaporator is fitted with a feed-water heater or economiser, which is constructed on the injector principle and may, if necessary, be supplied with fresh steam in addition to the vapour issuing from the last evaporator.—B.

II.—FUEL, GAS, AND LIGHT.

The Origin of Petroleum. Sickenberger. Chem. Zeit. 1891, 15, 1582—1583.

In support of the animal origin of petroleum, the author gives in detail an account of his observations with regard to the connexion he believes he has traced between the excessive animal life, and consequent animal remains in the Red Sea, and the tarry and bituminous matter found in the chalk on the coast.—A. R. L.

Fuel Gas; its Production and Distribution. A. Kitson. Jour. Franklin Inst. 1891, 132, 424—448.

THE author discusses at some length the comparative value of producer-gas, water-gas, and semi-water-gas, and strongly advocates the employment of the last-named as being the cheapest gas, provided it is supplied within a reasonable distance from the place of production; he believes that, allowing for all contingencies, it is possible to obtain from 2,240 pounds of anthracite from 150,000 to 160,000 cubic feet of semi-water-gas, averaging 165 heat units to the cubic foot, which will contain 25 million units of potential heat, or about 83 per cent. of the heat energy of the coal itself.

The cost of production of semi-water-gas is trifling, and the labour attached to its manufacture very slight; with coal at 3 dollars per ton its cost should not exceed 2½ cents per 1,000 cubic feet, that is to say, one million heat units at a cost of 15 cents.

The objections that are urged against the use of semi-water-gas are (1) that the presence of such a large proportion of non-combustible gases (nitrogen and carbon dioxide) necessitates the use of large pipes; and (2) that combustion is maintained with difficulty. The first objection only applies where it is absolutely necessary to use pipes already existing, as, in laying a new service, it would not matter much whether a 9-inch pipe had to be laid instead of a 6-inch pipe, for example; the second objection is confined almost entirely to producer-gas, because the combustion of semi-water-gas is readily maintained, especially when it is heated prior to ignition.

Not the least of the advantages which semi-water-gas, or "steam-jet" producer-gas, as it is sometimes called, possesses over water- or coal-gas, is the ease and simplicity of its production. It can be made in a furnace not much larger than some that are in use for heating dwellings, it requires no storage, is automatic in its production, and can be made in quantities varying from 500 cubic feet, to an indefinite quantity, per hour.

The apparatus designed by the author for the production of semi-water-gas, and which has been in use for some time driving a Körting gas-engine, is described (see this Journal, 1890, 48).

The Kitson gas generator occupies about 10 sq. ft. of floor space, and stands 8 ft. from the floor to the top of the feed hopper; it will give 1,500 cubic feet of gas per hour. It consists of a cylindrical shell of boiler iron, lined with brickwork, the internal diameter of the brickwork being 21 in., and the height from the grate to the top of the furnace 3 ft. 6 in.; the grate is connected on one side with a steam and air injector, on the other with the gas supply pipe, and is surrounded by a cast-iron box, which forms the ashpit, and which is securely fastened to the cylindrical shell; the whole apparatus is supported on four cast-iron legs. The ash box terminates in a mouth piece, which is opened and closed with a valve worked by a lever from the outside, and serves to dump the ashes whenever necessary without interfering with the process of gas making. The top of the furnace is closed by an iron plate on which is fastened the hopper, openings in the plate being provided for a pipe leading to the chimney, and for a connexion leading to a gas supply pipe, both pipes being provided with valves. A small reservoir, forming the boiler, is placed on one side; it communicates with two coils contained in the brickwork, the lower of which generates steam, whilst the upper one acts as a superheater. An injector is

provided at the top of the furnace, and air channels are arranged spirally in the brickwork through which air is drawn by the injectors. The walls of the furnace are inclined inwardly towards the top so that the entire weight of the fuel is thrown on the grate; the grate is provided with mechanism for giving it a rotary and an up-and-down motion, the effect of which is to break up any clinker, to keep the coal in a compact mass, and to throw the dust and ash into the ash pit.

The author claims that this form of generator is cheap in construction and economical in working; it can be made small enough to produce 500 cubic feet of gas per hour, which means a consumption of only six or seven pounds of coal. It is also easily set up, taken down, and removed; there is no danger from fire or explosion, and it requires but ordinary care, as in the case of a common coal furnace.

—F. S. K.

PATENTS.

Improvements in and connected with Apparatus for Burning Hydrocarbon or other Oils for Heating and Lighting Purposes. G. Rose, Glasgow. Eng. Pat. 829, January 16, 1891.

THIS specification proposes improvements in apparatus described in patent No. 18,101, 1889 (this Journal, 1890, 1025) in which hydrocarbon ores are burned by aid of steam generated from water supplied to a coil pipe heated by the flame.

A single tank divided into two compartments or two separate tanks may be used, a pipe leads from the reservoir containing oil to the burner, and another pipe leads water from the other tank or division to the steam generating coil. The steam is led from the coil to the burner to spray the oil.

A sheet of drawings accompanies the specification and illustrates the details of the application of this invention to rivet heating, anapola, and other furnaces or boilers.

—D. A. S.

Improvements in the Treatment and Desiccation of Peat. W. P. Thompson, Liverpool. From J. M. A. Gérard, Paris, France. Eng. Pat. 5036, March 20, 1891.

IT is proposed to produce from peat, rapidly and economically, a dense agglomerated fuel which may be used in every kind of furnace. The blocks of peat from the turf pit are immersed in water and are subsequently raised by an elevator to a horizontal pug-mill where the peat is thoroughly disintegrated. The peat, in the form of a fluid paste, is led into purifiers where impurities, such as sand and clay, are separated by gravity. The paste is then spread on an endless metal gauze band travelling on cylinders arranged in a horizontal frame, and by means of a cam shaft receives a series of shocks to assist the drainage. On leaving this frame a second endless wire gauze band is led over as a cover and continues to circulate throughout the subsequent operations, thus carrying the peat enclosed.

The bands pass through rolls and other suitable arrangements to press out as much water as possible, and travel subsequently through a drying stove maintained at a temperature high enough to drive off the gas and volatile matter and partially carbonise the peat, the tar is, however, retained to aid in the agglomeration and combustion.

On leaving the furnace the bands separate, the peat being removed by means of revolving brushes, is led to a mill, where after being mixed with agglomerating substances it is finally moulded into briquettes. The process is continuous, but may be varied according to the quality of peat used. A drawing of the apparatus is attached to the specification.—D. A. S.

Improvements in and connected with Gas Retorts. W. T. Cotton, London, and E. F. B. Crowther, Manchester. Eng. Pat. 6947, April 22, 1891.

THIS invention relates to certain improvements in gas retorts by which it is rendered possible to take the gaseous products from the top of the retort to the hydraulic main,

and also to charge the retort directly from an overhead tram or railing by a very simple apparatus.

The retort is built in the stack in an inclined position, and its lower end is closed by a suitable lid. The upper extremity is provided with two lateral openings close to the end of the retort; one of these openings is connected with a vertical pipe leading to the hydraulic main. The other opening is closed with a suitable lid, directly over which can be brought a hopper or vessel containing the charge, and suspended on an overhead tram or railway. When the lid and the hopper valve are opened the coal falls directly into the retort. At the top end of the retort there is a third opening, through which, when the cover is removed, a rod may be thrust in order to clear away any coke or carbon deposit. The retort is inclined at such an angle that when the door at the bottom is opened the coke will fall out of the retort.—F. S. K.

Improvements relating to the Manufacture of Gas from Hydrocarbon Oils, and to Apparatus therefor. H. H. Lake, London. From C. H. Wilder, Boston, U.S.A. Eng. Pat. 18,498, October 27, 1891.

THE object of this invention is to provide a process for feeding oil or any other hydrocarbon liquid to a vaporising retort in such a way that sediment and other foreign matter present in the oil may be deposited before the oil is passed into the retort.

This is effected by heating the oil in a tank which is partially filled with water, and then forcing it by hydrostatic pressure, together with a suitable proportion of air, into the vaporising retort; in this way not only is the oil fed uniformly into the retort, but it is also purified by direct contact with the hot water, the sediment being drawn off by a pipe at the bottom of the vessel. The vaporising retorts are coated inside with a pasty mixture of plumbago and molasses, which on heating forms a protecting covering of fixed, practically indestructible carbon.—F. S. K.

Improvements in the Manufacture of Gas and in Apparatus to be used therein. T. G. Springer, Chicago, U.S.A. Eng. Pat. 19,641, November 12, 1891.

IN the manufacture of a fixed illuminating gas from water-gas and oil or liquid hydrocarbon it is evident that oils of high specific gravity will require a higher temperature for their complete vaporisation than those of low specific gravity. According to this invention the vaporisation of the oil is effected by providing a vaporiser quite independent of the water or steam gasifier, so that the temperature may be regulated according to the specific gravity of the oil.

The vaporiser described consists of a retort, heated directly by a furnace of its own; the oil is delivered directly from a ring pipe into the top of the retort, the sides of which are inclined inwards and downwards, so that the oil is caused to flow in a thin film down the heated walls, the impurities being at the same time directed towards the bottom, whence they can be readily removed. The fixing chamber may advantageously contain trays filled with lime, which removes some of the carbonic acid present; on reheating, the carbonic acid is driven off and the lime is rendered capable of again acting as a purifier.—F. S. K.

Improvements in Manufacture of Gas. G. M. S. Wilson, Toronto, Canada. Eng. Pat. 535, January 11, 1892.

THE improved apparatus consists of a series of retorts arranged in such a way that a mixture of air, steam, and oil is exposed for as long a time as possible to a uniform heat; the result of this treatment is that practically the whole of the hydrocarbon vapour is fixed, and the gas obtained is exceptionally clean and free from readily-condensable vapours.

There are five retorts, three of which are placed close together and occupy the whole width of the inside of the

furnace; the upper surfaces of these retorts form the bed for a fire which not only serves to heat the retorts but also to heat the steam boiler. Below the retorts just mentioned are placed two others, heated by a fire underneath. The oil, steam, and air are introduced through pipes and jets into the ends of the two outer top retorts; the mixture passes the whole length of these retorts and is then conducted by elbows to the two lower retorts; after traversing the whole length of the latter the two streams are united and passed first into the centre top retort, and finally through a smaller tubular retort supported centrally in the larger one; the fixed gas then flows into the discharge pipe. Each retort is provided at its end with a removable plug so that it can be easily cleaned out should any accumulation of carbon take place.—F. S. K.

Improvements in Machinery or Apparatus for Effecting the Complete Mixture of Inflammable Gas or Vapour with Air. W. E. Vickers, Surbiton, and G. A. Everett, London. Eng. Pat. 965, January 18, 1892.

THE machinery or apparatus described in this patent consists essentially of a number of force pumps by means of which air and an inflammable gas or vapour are first forced together through a single pipe into the lower end of a chamber A: the mixture then passes through a large number of small holes or jets in the walls of the chamber A and impinges on the inner walls of a somewhat larger chamber B, which surrounds the perforated chamber A. The mixture, which is in this way rendered very intimate and permanent, finally passes out of the chamber B through a delivery pipe. The pistons of the force pumps are driven by adjustable eccentrics, so that the quantity of air and of inflammable gas or vapour can be conveniently and accurately regulated.—F. S. K.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

PATENTS.

Improvements in Means and Apparatus for Refining Paraffin. J. and W. Baxter, Addiewell. Eng. Pat. 4321, March 11, 1891.

THE improved process described relates to the refining of paraffin wax, and consists in placing the cakes of paraffin on their edge inside a wire cloth case which may be lined with canvas; the cases are secured (a space being left between each) to carriages running on wheels with rails or guides on each side, top and bottom. The carriages are connected together by an endless pitch chain, and after being charged are run by means of the pitch chain at the desire of the operator. The sweating chamber is heated with steam pipes suitably placed. It is claimed that by sweating in this perpendicular manner, the heat being aided by the pressure of the paraffin itself, the impure matter flows more freely from both sides of the cake and a better result than hitherto can be obtained.

After the sweating is completed the carriages are run on and passing under are inverted and so discharge their contents mechanically into a finished product tank.

In the accompanying drawings Fig. 1 is a side elevation, and Fig. 2 the end elevation, a^1 and a^2 show the carriages, g the pitch chain passing round notched wheels $e e$, fixed to shafts $f f$, mounted on bearings on a frame mounted on pillars i ; k is the tank for receiving the discharged finished product, $d d$ the rails, j a saucer beneath the carriages to carry off the impure matter, $l l$ steam pipes, the inlet being

Fig. 1.

Fig. 2.

IMPROVED APPARATUS FOR REFINING PARAFFIN.

at *g* and outlet at *o* after passing through the tank *k*. The operator can cause the carriages to revolve at will by setting the chain in motion. The whole of the apparatus is erected on and embedded in brickwork shown at *h*.—D. A. S.

PATENT.

Improvements in Cauldrons for Melting Pitch and Fatty Substances. B. D. Henley, Bamber Bridge. Eng. Pat. 324, January 7, 1892.

See under XII. page 446.

IV.—COLOURING MATTERS AND DYES.

On the Constitution of the Ortho-hydroxyazo Compounds. S. Ganelin and St. v. Kostanecki. Ber. 1891, 24, 3976.

In many cases it is difficult to decide whether an ortho-oxazo compound contains a hydroxyl group, or whether its constitution is that of a hydrazone. Monohydroxylated colouring matters containing the hydroxyl group in the ortho position to certain atomic groups are capable of dyeing mordanted fibre. By substituting in such colouring matters

the quinone oxygen atom for the hydroxyl group the resulting compounds lose their affinity for dye mordants, so that probably the azo colouring matters containing respectively the above two isomeric groups will show the same difference in the dyeing test, and the latter would therefore be a very simple method to determine the constitution of a given ortho-oxazo compound. *Noelting* and *Trautmann* (Ber. 1890, 23, 3660) and *Kostanecki* (Ber. 1891, 24, 150; this Journal, 1891, 356) found ortho-oxoquinoline to dye mordanted cotton, while ana-nitroso-ortho-oxoquinoline—

had lost this property. The same difference is likely to exist between the two corresponding ortho-azo derivatives of ortho-oxoquinoline, viz.:—

Anaphenylazo-ortho-oxoquinoline being a para-azo derivative is sure to contain a hydroxyl group, and this compound the authors found to dye yellow upon an alumina mordant, brown on an iron mordant. In order to obtain an ortho-azo compound of ortho-oxoquinoline the authors used *Noelting* and *Trautmann's* ortho-hydroxyanamethylquinoline—

Metaphenylazo-ortho-hydroxyanamethylquinoline—

This azo compound was obtained by adding to a solution of diazobenzene chloride a corresponding quantity of ortho-hydroxyanamethylquinone dissolved in hydrochloric acid. On addition of alkali the colouring matter is precipitated and recrystallised from glacial acetic acid, when it is obtained in the form of carmine-coloured needles, melting at 120° C., insoluble in cold water, very little soluble in hot water. Alkalis dissolve only very small quantities, concentrated sulphuric acid dissolves the substance, forming a yellowish-red solution. This compound dyes a yellowish-red on alumina mordant and a dark brown on iron mordant, which goes to prove that it is an azo compound and not a hydrazone.

Meta-amido-ortho-hydroxyquinamethylquinoline—

On treating the above described azo compound with tin and hydrochloric acid the hydrochloride of this compound is obtained, crystallising from hot water in large prisms. Carbonate of soda precipitates the free base, which crystallises from benzene in thick broad needles, melting at 139° C.

According to the theory of the authors the azo compounds of such hydroxyquinolines as do not contain a hydroxyl group in the ortho position to the nitrogen of the pyridine ring should be incapable of dyeing on mordants. On testing *Mathews'* phenylpara-hydroxyquinoline, in accordance with this theory, it was found unable to dye mordanted cotton.

This shows that the colouring matters of the quinoline series and also the hydroxyazo compounds of the quinoline series are in perfect accordance with the theory advanced for all other mordant dyeing colouring matters.—C. O. W.

On Acetyl-Indigo White and Acetyl-Indigo. C. Liebermann and F. Dickhutt. Ber. 1891, **24**, 4130.

TREATING indigo with a mixture of zinc dust, sodium acetate, and acetic anhydride (Ber. **21**, 442 (*footnote*); this Journal, 1888, 205), di-acetyl-indigo white—

is obtained, whereas Baeyer's indigo-white formula—

would lead us to expect the formation of the tetracetyl compound. This latter, however, the authors failed to obtain under the above-mentioned conditions.

On heating a solution of di-acetyl-indigo white in acetic anhydride with a drop of nitric acid (1·20 sp. gr.), the mass assumes a beautifully red colour. The same reaction is obtained by using, instead of nitric acid, bromine, chlorine, or chromic acid. This reaction therefore is evidently due to an oxidation, resulting in the formation of di-acetyl-indigo—

This substance is best obtained by suspending di-acetyl-indigo white in 70 times its weight of acetic anhydride, and passing through the mixture a current of nitrous acid. The reaction may be accelerated by gently warming, and is completed as soon as the mass shows a bright red colour. After filtration, the di-acetyl-indigo soon crystallises out in the form of fine carmine coloured flitters.

The substance is insoluble in water, and with great difficulty soluble in most of the ordinary solvents; it is best recrystallised from benzene. On heating with dilute alkalis the substance is easily and quantitatively converted into indigo. Di-acetyl-indigo dissolves in concentrated sulphuric acid, with a green colour which, on heating, changes into through formation of indigo-sulphonic acid. These reactions leave no doubt as to the constitution of di-acetyl-indigo white and di-acetyl-indigo.

Di-acetyl-indigo may be obtained direct by treating a boiling mixture of indigo and acetic anhydride with acetyl chloride. In place of the latter, hydrochloric acid may be employed, but in this case the reaction proceeds much more slowly.

In the above described di-acetyl-indigo white the acetyl groups are attached to the nitrogen atoms, and accordingly, that compound ought to contain two unaltered hydroxyl groups, which would render it soluble in alkalis. But this

di-acetyl compound, being insoluble in cold alkalis, belongs probably to the class of tautomeric forms of indigo compounds (Bayer's ψ -forms)—

in which the hydrogen is attached to the two central carbon atoms instead of to the carboxyl groups.

Tetra-acetyl-indigo white, $\text{C}_{16}\text{H}_8(\text{C}_2\text{H}_3\text{O})_4\text{N}_2\text{O}_2$. This compound was obtained by treating di-acetyl indigo with a mixture of zinc dust, acetic anhydride, and sodium acetate. It is a colourless substance, which crystallises from its solution in boiling acetic anhydride in the form of a sandy powder. On boiling the substance with dilute alkali, indigo is obtained. Concentrated sulphuric acid dissolves it with a green colour, which on heating turns blue.

Tautomeric (β -) di-acetyl-indigo white—

was obtained by carefully heating a mixture of acetyl indigo (17 parts), phenylhydrazine (11 parts), and a small quantity of benzene. Evolution of gaseous nitrogen takes place, and at the same time a white, crystalline substance begins to separate out, which is the above-named compound. It differs from the first described di-acetyl-indigo white which is crystalline, by its indifference to nitrous acid which does not convert it into acetyl indigo, and its capability of dissolving in cold alkalis, thereby forming an indigo vat. This β -di-acetyl-indigo white is therefore—

This formula is confirmed by the fact that on treatment of this compound with acetic anhydride and sodium acetate the identical tetra-acetyl-indigo white is obtained, which has already been described above, and the formula of which must be accordingly—

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

On Fibres made from the Leaves of Fir Trees. F. v. Hühnel. Centr. Org. f. Waarenkunde u. Techn. 1891, **1**, 144; and Chem. Zeit. Rep. 1891, **15**, 218.

ALL experiments to obtain good textile fibres from the leaves of European firs, especially *Pinus silvestris*, have been more or less unsatisfactory, as the product obtained called "pine-wool" (*laine végétale*, *Waldwolle*) consists of coarse, short, brownish fibres of little elasticity, which are not easily spun and bleached. If the leaves of *Pinus silvestris* are examined microscopically, they show an epidermis which is almost twice as thick as the hypodermal layers, and most of the leaves have a length of only 4 to 7 cm. Hence the fibres of *Pinus silvestris* are unfit for spinning. But some American species of firs, especially the so-called yellow pitch or bruce pine (*Pinus australis*) and the Loblolly pine (*Pinus Taeda*) seem to yield much more suitable fibres. Their leaves are 16 to 35 cm. long, and a microscopical examination shows that the epidermis is much less developed, being only one-half or one-third the thickness of the hypodermal layers. Moreover the latter

are mostly separated from the epidermis by a layer of cells with thinner walls, and the fibres are longer and stronger. The consequence is that this American pine-wool is often free from epidermis, and therefore much better adapted for textile fabrics. The coarse American pine-wool is used for upholstering and similar purposes. The finer kinds unbleached are light brown, bleached, of a yellow colour, and may be used for coarse yarns in the manufacture of common carpets, sacking, &c.—H. S.

Properties of Ammoniacal Copper Hydrate. Prud'homme. Monit. Scient. 1891, 5, 681.

AMMONIACAL copper hydrate is an oxidising agent. This is proved by its bleaching action on cotton dyed a medium shade of indigo blue. Such cotton, when immersed in a solution of the reagent which has been sufficiently diluted to prevent its attacking the fibre, is decolourised in 24 hours; at 60° C. the decolourisation is complete in a few minutes. In this instance the oxidising effect of the ammoniacal copper solution is greater than that of hydrogen dioxide, which has little action on indigo. Again, when cotton is treated for a short time with a concentrated solution of ammoniacal copper, then well rinsed and treated with dilute acid (to remove copper hydrate) it possesses a strong attraction for Methylene blue, showing its conversion into oxycellulose.

Ammoniacal copper attacks and dissolves mercerised cotton more rapidly than it does ordinary cotton (this Journal, 1891, 835). As prepared by agitating copper turnings with ammonia solution, ammoniacal copper hydrate contains ammonium nitrite, as Berthelot and Péan de Saint-Gilles have pointed out. At the commencement of the operation, however, the blue solution obtained is free from nitrite, the latter being formed gradually in contact with air. Its formation may be observed by taking successive portions of the solution, faintly acidifying with hydrochloric acid, and adding aniline hydrochloride and an alkaline solution of α -naphthol, an orange colour being produced. Metallic copper acts in the cold upon a solution of ammonium nitrite, liberating nitrogen dioxide (red fumes) and afterwards ammonia—

In the presence of ammonia, nitrogen is evolved—

In both cases the liquid rapidly takes a blue colour. On the addition of a sufficient quantity of water to this solution, or to the ordinary solution of ammoniacal copper, cupric hydrate is precipitated. The blue solution in contact with copper in a closed vessel becomes colourless, and then contains cuprous oxide, since, on the addition of sulphuric acid, copper sulphate is produced along with a precipitate of metallic copper. The final composition of an ammoniacal copper solution evidently depends upon the extent to which the above actions take place.—E. B.

Action of Nitric Acid on Silk. L. Vignon and P. Sisley. Compt. Rend. 1891, 113, 701—704.

See under VI., page 430.

The Rotatory Power of Silk. L. Vignon. Compt. Rend. 1891, 113, 802—804.

ACCORDING to its chemical constitution silk ought to be classed amongst the albuminoids. Heated with dilute sulphuric acid, leucine and tyrosine are found amongst the decomposition products. Leucine is (optically) inactive, but by the action of *Penicillium glaucum* is changed into an active modification. Tyrosine is active and levo-rotatory.

The author's intention was to determine whether silk itself had any action on polarised light, and at first great difficulty was experienced from lack of a suitable solvent. This has been surmounted and the optical behaviour of the sericin and fibroin, separately studied.

I. Sericin.—After removing the natural colouring matter of the silk by means of alcohol containing a little hydrochloric acid the sericin was dissolved off with sodium hydrate (3 per cent. solution). This did not sensibly attack the fibroin.

(a.) After filtration, the slightly yellowish solution of sericin was immediately examined by a Laurent polarimeter, using the yellow monochromatic sodium light. A very clear deviation to the left was noticed, five observations giving an average—

$$-1^{\circ}43' = -1^{\circ}71$$

from which is deduced—

$$(x)_d = \frac{1^{\circ}71 \times 100}{2 \times 2^{\circ}20} = -38^{\circ}8.$$

(b.) 10 cc. HCl 32° Tw. were added to 20 cc. of the sericin solution, giving a clear strongly acid liquid deviating—

$$-1^{\circ}16$$

whence—

$$(x)_d = \frac{-1^{\circ}16 \times 150}{2 \times 2^{\circ}20} = -39^{\circ}5.$$

(c.) 10 cc. of distilled water added to 20 cc. of the original solution, gave $-1^{\circ}15$ to the left, corresponding to—

$$(x)_d = \frac{-1^{\circ}15 \times 150}{2 \times 2^{\circ}20} = -39^{\circ}2.$$

The rotatory power is slightly augmented by dilution, but the acid or alkaline character of the solution appears to exert no influence.

II. Fibroin.—To ensure the complete removal of the sericin (silk glue) the silk was “boiled off” twice with soap, and then thoroughly washed with water, acid, and alcohol. After drying it was dissolved in concentrated hydrochloric acid, the solution taking place very rapidly, forming a viscous homogeneous liquid. After diluting with water and filtering, this solution was examined by the polarimeter.

(a.) The acid liquid gave an average deviation of $-3^{\circ}17$ corresponding to—

$$(x)_d = \frac{-3^{\circ}17 \times 200}{2 \times 7^{\circ}33} = -39^{\circ}96.$$

(b.) When diluted with an equal volume of distilled water the solution is not precipitated. Its deviation then becomes $-1^{\circ}64$, from which—

$$(x)_d = \frac{-1^{\circ}64 \times 200}{2 \times 7^{\circ}33} = -41^{\circ}30.$$

(c.) The original liquid diluted with its own volume of ammonia gave a limpid solution, the deviation of which is $-1^{\circ}73$, from which we deduce as before—

$$(x)_d = \frac{-1^{\circ}73 \times 200}{2 \times 7^{\circ}33} = -42^{\circ}80.$$

Therefore dilution again slightly increases the rotation, but the values are found little different in acid or alkaline solution. It will be noticed that the numbers given by the fibroin solution are very near those of the sericin, and also approximate to those of other albuminoids.

The solution of fibroin in hydrochloric acid becomes yellow on adding nitrous nitric acid like other albuminous substances. By neutralisation a substance is deposited which appears identical with the original silk, but possesses the additional property of being easily and completely soluble in ammonia.

In conclusion, the author summarises his results, stating that the solutions of the two principal constituents of silk from *Bombyx mori*, i.e., sericin and fibroin, both exert a considerable action on polarised light; the action of both being levo-gyrate, and the rotatory power in each case being very near, -40° .—W. M. G.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

On the Methods of Increasing the Tinctorial Properties of Dye-Wood Extracts. V. H. Soxhlet. Chem. Zeit. 1891, 15, 1490—1491.

THE treatment of logwood-extract with ammonia and subsequent neutralisation with sulphuric acid (McFarlane and Clarkson) heightens the shade imparted to woollen fibres, but does not alter that imparted to vegetable fibres; even in the former case the increase in brightness is not permanent. This method is of no value to the extract manufacturer, as the extract must be treated at a density of 0.5 B., and on concentrating *in vacuo* decomposition occurs. The American process, which consists in the oxidation of hematoxylin to hematein gives fair results, but it is not likely to find favour with the extract manufacturer. The use of potassium permanganate with the extract has been abandoned because the product is not available for dyeing wool. After numerous experiments with different salts, the author found that all those extracts which are oxidised during the extraction, possess less intense tinctorial powers than when such oxidation is avoided. Chalk, borax, soda, &c. should not be present during the extraction, but may be subsequently added to the vacuum evaporation apparatus which is conveniently heated by a glycerol-bath.

When logwood is extracted in the presence of 0.05 per cent. of potassium nitrate and rock-salt, and 0.013 per cent. of a "bisulphite solution" of 40° B. (the percentages calculated on the logwood), and extracted at a pressure of 1.5 atmospheres, the shades produced are weaker than those obtained by extracting the logwood *per se*. On the other hand, when an oxidising agent is added to the dye-bath, cotton mordanted with iron, and wool boiled with bichromate and sulphuric acid, are dyed much brighter, the most intense shades being obtained by adding potassium nitrate and bisulphite to the bath. Borax, ammonia, water-glass, and soda give good results; the first, however, is not easily miscible with the extract, and the others by protracted action decompose it. By employing sodium chlorate in cotton-printing a shade of 10 per cent. more intensity is produced; whilst by the addition of potassium ferricyanide, wool mordanted with bichromate gives a bluish black 15 per cent. more intense than without it, *i.e.*, 15 per cent. more of the pure extract must be used to produce an equal depth of colour. The logwood is cut into transverse pieces avoiding the production of too much dust, and the author employs a battery of five copper extractors, four of which are filled with logwood, and are extracted five times under a pressure of 1.5 atmospheres for 15 minutes, whilst the remaining extractor is filled with boiling water and kept at a certain pressure; it serves to supply the others with water. The extractor is now recharged with logwood and the boiling extract having a density of 0.5 B., and boiling water together with one of the previously mentioned salts added; it is then allowed to settle in a tank, evaporated to a density of 30 B. in a vacuum apparatus, and mixed with the requisite quantity of potassium ferricyanide. The same method gives equally good results with Brazil-wood, fustic, and quercitron bark as with logwood.

Silk-blue is obtained as a paste of a golden lustre by precipitating a logwood extract with aluminium acetate and treating the precipitate with hydrochloric acid.—A. R. L.

On the Oxidation of Wool Fibres and a New Treatment of Unprepared Wool in Wool-Printing. Chem. Zeit. 1891, 15, 1674—1675.

It is a well-known fact that wool fibre may reduce substances which readily give off oxygen. This property is of importance for the application of colouring matters. Some time ago, V. H. Soxhlet found that if woollen yarns are treated with a potassium permanganate solution of 7 per cent. strength, and then dyed in the indigo vat, the shade is much darker than by the ordinary treatment, and the

author is inclined to think that this is due to an oxidation of the wool fibre by the permanganate. A series of experiments in which wool was treated with potassium permanganate of 7 per cent. strength, to which 1 per cent. of magnesium chloride was added, and afterwards dyed with different colouring matters (*e.g.*, Amaranth, Ponceau, Victoria-blue, &c.), showed, however, that in most cases the treatment with the permanganate is of little advantage. Also for printing on wool the application of permanganate proved unsatisfactory; but the author discovered that if sodium chlorate (6.67 per cent.) and vanadium dichloride (0.2 per cent.) are added to the dyes, darker shades are obtained by printing on unprepared wool than if wool prepared with chlorine be treated with colouring matters without these additions. Unfast dyes, *e.g.*, Amaranth, are an exception, as printing with them gives more intense shades on prepared wool. This new treatment has the advantage that the wool remains soft and white. If the dyes are allowed to stand for more than 10 or 14 days, with the above specified additions decomposition sets in; they should therefore be mixed shortly before use. By a further addition of acetate of tin (4 per cent. of 5½° B.) still more intense shades may be obtained.—H. S.

Indigo and its Application in Dyeing and Printing.
A. Wöcher. Zeits. f. angew. Chem. 1891, 731—738.

INDIGO is obtained from several species of leguminous plants indigenous to the tropics, the most valuable being *indigofera tinctoria*, *disperma*, *anil*, and *argentea*. Where its manufacture is carried on by natives, as it is in the main still, the yield and quality of indigo obtained are generally unsatisfactory. The factories directed by Europeans obtain a better yield and superior product. In India three crops of plants are obtained during the year. The land is sown in March and the plant-stalks cut down for the first time early in June, a second crop being collected in September, and a third in January. To separate the indigo, the plants are steeped in lime-water, when a fermentation takes place with the formation of leuco-indigotine. The solution of the latter is run into a tank situated at a lower level than the extraction tank and well agitated to oxidise the leuco-compound, the indigo formed being afterwards separated by subsidence and dried. The first crop of plants gives the greatest yield of indigo, the third the least. In regard to quality, however, this order is reversed, the indigo obtained from the third crop being the best. Usually the plants are extracted immediately after cutting; sometimes, however, they are first dried in the sun. In the latter case they must be extracted along with freshly-cut plants, as a ferment which causes the formation during extraction of leuco-indigotine is contained in the living plant and is destroyed by drying.

The author points out that definite proof is lacking that indigotine is present in the plant in the form of glucoside (indican), as it is usually assumed to be, indican having been isolated from woad (*isatis tinctoria* of the order Cruciferae) alone. If such a glucoside be contained in the indigo plant, indigo could be readily manufactured by decomposition of the aqueous extract with dilute acid.

The various qualities of indigo sent into the market are distinguished by the names of their places of manufacture. This, however, is an unsatisfactory method of classification, since the quality of the product varies according to the season of manufacture, and in one and the same district, according to the greater or less care exercised in its manufacture. Of the various sorts, that from Java is the most esteemed, as it contains a high percentage of colouring matter—a sample tested by the author showing 74 per cent.—with little or no organic impurity. This quality is chiefly employed for the manufacture of indigo-carmin. Bengal indigo is very variable; the best qualities are not inferior to Javanese, the worst are very hard and of little value. Bengal indigo frequently contains a considerable proportion of red and brown colouring matters which give it an additional value for dyeing dark bronzy shades. An average sample of it contains about 60 per cent. of colouring

matter. Madras sorts, on the whole, are inferior to those of Bengal manufacture. Guatemala indigo is unreliable, consisting, as it usually does, of good and bad qualities mixed together. A sample tested showed 34 per cent. of indigotine. Chinese indigo, as a rule, is of good quality; it is exported in the form of rounded cakes, sometimes in a wet state. African and Egyptian indigos are of moderately good quality.

The total annual production of indigo amounts to about 10 million kilos., representing a value of about 90 million marks.

Testing of Indigo.—The following modification of the permanganate test gives satisfactory results in cases where the indigo contains little organic matter other than indigotine and indirubin, and in all cases is very suitable for testing indigo which is intended for the manufacture of indigo-carmines:—1 grm. of a finely-powdered sample of the indigo is placed in a beaker of 50 cc. capacity, and mixed with 8 cc. of fuming sulphuric acid containing 10 per cent. of anhydride. The mixture is heated on a sand-bath to 50°–60° and well agitated. At the end of two or three hours, the solution obtained is rinsed into a litre-flask, and the latter filled to the mark. 100 cc. of this solution are then taken, mixed with 400 cc. of water and 50 of dilute (1:10)

sulphuric acid, and titrated with decinormal permanganate solution until the blue colour has entirely disappeared. The result is calculated on the basis of 1 cc. of the permanganate solution oxidising 7.415 mgrms. of indigotine.

Syntheses of Indigo.—The methods of manufacture discovered by Baeyer (this Journal, 1882, 17, 24 and 146) and Heumann (this Journal, 1890, 1121, and 1891, 41) are too costly to be industrially successful. Heymann's synthesis of indigo-carmines (this Journal, 1891, 758 and 827) is more practicable, both on account of its offering fewer difficulties in carrying out on the large scale, and on account of the greater yield, amounting to 60 per cent. of the weight of phenylglycocine, obtained.

Indigo Dyeing.—The application of indigo in dyeing is based on its conversion by the action of alkaline reducing-mixtures into leuco-indigotine, which dissolves in the alkali present. For this purpose there are variously used: lime, caustic soda, ammonia, and alkaline carbonates, along with ferrous sulphate, zinc powder, iron filings, sodium hyposulphite, stannous chloride, sodium xanthate, thiourea, arsenious oxide, and glucose. For wool-dyeing, vats are also prepared by the action of certain ferments. The composition of such fermentation vats is shown in the following table:—

Name of Vat.	Indigo.	Wool.	Madder.	Bran.	Turnips (sliced).	Quick-lime.	Potash.	Soda Crystals.	Caustic Soda.	Flour or Starch.	Glucose.	Magnesia.	Water.
	Kilos. 12–15	Kilos. 150–200	Kilos. 5–10	Kilos. ..	Kilos. ..	Kilos. 4–6	Kilos. ..	Kilos. ..	Kilos. ..	Kilos. ..	Kilos. ..	Kilos. ..	Litres. 8–10,000
Wool.....	12–15	150–200	5–10	4–6	8–10,000
Indian.....	8–10	..	4–6	5–6	10	4–5,000
German.....	6–8	..	0–4	50–60	..	2–4	..	12–15	4–5,000
Combination.....	6–8	50–100	8–10	20–25	..	4–5	6–8	6–7,000
Benoist and Collin's	8–10	1.6	5.4	16	8	1	8,000
Peptin.....	5	200–300	6–8	5,000

Most of these vats have been in use a long time, and although recently the theory of the action taking place in them has been better understood, no improvement of moment has been made in them. According to recent investigations, hydrogen is liberated by the action of the ferment-bacteria, the carbohydrates present being converted first into lactic acid and then into butyric acid, carbon dioxide, and hydrogen. This action takes place best in the presence of a moderate excess of alkali. Too much alkali hinders it, too little encourages a rapid and destructive fermentation.

The fermentation vats are being gradually replaced for wool-dyeing by the hyposulphite vat. In practice the turbid acid mixture resulting from the action of zinc on a solution of sodium bisulphite is directly used for reducing the indigo. Sometimes, however, a clear and more stable solution of sodium hyposulphite is prepared by adding milk of lime to this crude hyposulphite solution and allowing it to settle, when zinc hydrate and calcium sulphate are precipitated along with the excess of lime. With the hyposulphite, a concentrated indigo solution or vat is prepared and added to the dye-vat in the required amount. The alkali thus introduced into the vat is not absorbed by the material which is dyed, and tends to gradually accumulate. As an excess of it renders the vat inoperative besides injuring the wool, its increase must be checked from time to time by addition of hydrochloric acid or of the crude acid hyposulphite solution mentioned above.

The hyposulphite vat is less used for cotton-dyeing than those prepared with copperas and zinc dust. Zinc dust has the advantage of giving a much clearer vat than copperas, and so enables the dyer to employ shallower or smaller vats.

Substitutes for Indigo.—Indigo shades are closely imitated on linen and cotton by Paraphenylene blue, Indoine, Metaphenylene blue, Benzoazurin, and other dyes. Although not so fast as indigo, they have the advantage

over the latter of being fast to rubbing. The fulness of colour, characteristic of dark shades of indigo, cannot, however, be obtained with these dyes when employed alone, but is frequently obtained by first dyeing with them and then with a small quantity of indigo. For dyeing wool dark blue Alizarin-blue is very extensively employed, but is inferior to indigo in its resistance to light.

Substitutes for Indigo-carmines.—Indigo-carmines is extensively employed in the dyeing of woollen goods, as it possesses the property of dyeing along with other acid dyes and is useful for the production of compound shades. Recently two coal-tar dyes, Thiocarmine and Patent Blue, have entered into serious competition with it.

Application of Indigo in Printing.—Patterns in indigo are produced on calico either by printing reserves and dyeing, or by dyeing and then discharging the blue colour from certain parts, or again by directly printing with indigo. In the first method the entry of the leuco-indigotine into the fibre is prevented by such substances as kaolin, copper sulphate, copper acetate, tartaric acid, and alum. The last two compounds cause a superficial precipitation on the cloth of leuco-indigotine, which then acts as a mechanical resist. Discharge-patterns are produced by printing on the dyed cloth a thickened solution of sodium chromate, along with albumen and a pigment for colour-effects, and passing through a bath of sulphuric and oxalic acids. As pigments chrome yellow, orange, and green, vermilion, Prussian blue, and iron-oxide buff are used, with other pigments, which are capable of withstanding the action of chromic acid. White discharge-patterns are also produced by printing potassium ferricyanide and passing through caustic soda solution, as well as by printing a thickened mixture of a chlorate, potassium ferricyanide, and stannic oxalate and steaming for an hour. Beautiful effects are obtained by the chromic acid method, but the colours so printed are not satisfactorily fast as they are only superficially deposited and fixed with albumen, and again the fibre in the printed

part becomes more or less tendered through the formation of oxycellulose.

Of the numerous attempts made to print indigo directly, none has been so successful as the glucose process (this Journal, 1884, 52—62). An important extension of this process is its combination with the printing of chrome yellow and a mixture of indigo and chrome yellow in a Turkey-red discharge style. The Turkey-red cloth is padded with glucose, dried, and printed with a thickened mixture of indigo and caustic soda for blue, with caustic soda and lead oxide for yellow, and with indigo, lead oxide, and caustic soda for green patterns. It is then dried, steamed, washed, passed through dilute acid, again washed, and chromed.

Substitutes for Indigo in Printing.—Several very fast blues, giving shades resembling those of indigo, are employed in calico printing, but can scarcely be said to compete with indigo. Acetin blue and the so-called Printing blue (a spirit-soluble induline) are amongst the newest of these dyes.—E. B.

Action of Nitric Acid on Silk. L. Vignon and P. Sisley. Compt. Rend. 1891, 113, 701—704.

It is a well known fact that nitric acid imparts a yellow colour to albuminoids; and the authors, in specially studying the phenomenon in the case of silk, have made the following observations:—

I. The yellow colour is best produced by immersing the silk for about a minute in nitric acid diluted to 1·133 sp. gr. (26·6° Tw.) at 45° C. A characteristic deep yellow colour is immediately developed, which is retained on thoroughly washing with water. The colour is not readily affected by exposure to air and light, and is greatly intensified by steeping the silk in alkali, but restored to the original tint by acids. This yellow colour has been practically utilised in Lyons under the names "Mandani" and "Nitric acid" yellow.

II. Nitric acid free from nitrous acid does not produce any colouration under the above conditions.

III. Pure nitric acid with addition of a small amount of sodium nitrite gives a strong yellow colouration, which is intensified by increasing the amount of NaNO_2 , the concentration of the solution, and the temperature, but cannot be carried beyond a certain point without destroying the fibre.

IV. The colour obtained with the mixture of nitric and nitrous acids is also rendered darker by alkalis; a portion of the latter being permanently absorbed since a notable quantity may be detected in the ash left on incinerating the silk.

The shade of yellow obtained varies with the alkali employed, ammonia giving the lightest, and baryta water the reddest shade.

On the other hand the causticising of the alkali has no effect, NaOH and Na_2CO_3 , KOH and K_2CO_3 giving respectively the same shade.

The above experiments show that the presence of nitrous acid in the nitric acid is essential to the production of the yellow colour on silk. A second series of experiments was made with the object of studying the action more thoroughly.

I. Silk treated with nitrous acid ($\text{NaNO}_2 + \text{HCl}$) acquires a pale yellow colour which is not at all fast; the shade rapidly changing to pale brown on exposure to air or light. Boiling water or alcohol also changes the shade to brown without liberation of nitrogen. Alkalis develop a red-brown colouration.

II. A permanent yellow colour is readily produced from the unstable pale yellow obtained as above, by treating with pure nitric acid, the same effect being obtained upon silk previously treated with nitrogen dioxide (NO), or tetroxide (NO_2), in an atmosphere of carbon dioxide.

III. Permanganic acid ($\text{K}_2\text{Mn}_2\text{O}_8 + \text{HCl}$) develops a stable yellow colour on silk treated with nitrous acid, identical with that produced by pure nitric acid; the latter, therefore, acts simply as an oxidising agent.

The reaction which produces the characteristic stable yellow colouration upon silk requires the presence of NO , NO_2 or HNO_2 in conjunction with HNO_3 as an oxidising agent.

IV. Silk treated with nitrous nitric acid is slowly decolourised by a concentrated hot solution of stannous chloride or chromous chloride. Alkaline reducing agents have not the same effect.

V. Two examples of bleached Canton silk were submitted to elementary analysis after undergoing a preliminary purification by being "boiled off" with soap, washed with distilled water, dilute HCl , again with water, and finally with alcohol. After this treatment the ash only amounted to 0·023 per cent.

One hank was treated with nitrous nitric acid under the specified conditions, its weight thereby being increased about 2 per cent.

The numbers obtained on analysing the two samples were:—

	Purified Silk.	After Treatment with HNO_2 , HNO_3 .
	Per Cent.	Per Cent.
C.....	48·3	46·8
H.....	6·5	6·5
N.....	19·2	21·6
O (by difference).....	26·0	25·1

It will be noticed that after treatment the silk is richer in N, but contains less C and O, as would be expected from the above-mentioned increase in weight of 2 per cent.

The conditions of the treatment, and a consideration of analogous reactions, indicate that the nitrogen which has entered into combination was first fixed in the form of NO and afterwards changed by oxidation into NO_2 . It is improbable that the NO replaces hydrogen, the result of the analyses indicating that CO groups are eliminated, with formation of carbonic or oxalic acid.

The authors further state that wool acts in an exactly similar manner to silk when treated with nitrous nitric acid, and that their results differ materially from those obtained by Mûlder when preparing his xanthoproteic acid.

Nitrated silk does not deflagrate when burnt, but the combustion is quicker than with ordinary silk. It also smells like burnt feathers.

Towards solvents the nitrated silk behaves generally in the same way as ordinary silk, but when treated with concentrated sulphuric acid it swells up and gives a viscons mass similar to albumen.—W. M. G.

The Rotatory Power of Silk. L. Vignon. Compt. Rend. 1891, 113, 802—804.

A New or Improved Method of Manufacture of certain Compounds of Chromium used in Dyeing and Calico Printing. W. Watson and E. Bentz, Manchester. Eng. Pat. 3385, February 24, 1891.

CHROMIUM acetate, basic acetate, and sulphite, or mixtures of these salts, either alone or with chromium sulphate or basic sulphate, are prepared by reducing chromic acid in the form of sodium chromate or bichromate, with sodium sulphite or sulphurous anhydride in the presence of a suitable acid, such as acetic acid.

Chromium acetate is prepared by dissolving 112 lb. of commercial sodium bichromate in 550 lb. of 25 per cent. acetic acid, to which is then added gradually 400 lb. of 30 per cent. solution of sodium bisulphite, the temperature being kept down. The mixture is allowed to cool to allow the greater portion of the sodium sulphate to crystallise out, a further quantity of sodium sulphate being separated by the addition of 20 lb. of sodium carbonate or its equivalent of sodium hydrate.

Chromium basic acetate is prepared by employing one-half the above amount of acetic acid, the amounts of the other materials remaining the same.

Chromium sulphite is prepared by dissolving 112 lb. of sodium bichromate in 400 lb. of water, adding 39 lb. of 95 per cent. sulphuric acid, and then gradually 800 lb. of a 30 per cent. solution of sodium bisulphite, after which the mixture is allowed to cool until the sodium sulphate has crystallised out as far as possible. Instead of using sodium bisulphite, sulphurous anhydride may be employed in such quantity as is necessary to produce the salt of chromium which is required.

A mixture of chromium acetate and sulphate is obtained by acidifying the solution of sodium bichromate with a mixture of acetic and sulphuric acids, the amount of water used depending on the strength of these acids.

A mixture of chromium acetate and basic sulphate is prepared by the use of the same materials as in the preparation of a mixture of the acetate and sulphate, but the quantities of acetic and sulphuric acid are reduced, or the addition of sulphuric acid may be omitted, sufficient being formed from the sulphurous acid.

A mixture of chromium sulphite and sulphate is prepared by dissolving 112 lb. of sodium bichromate in 400 lb. of water, adding 60 lb. of 95 per cent. sulphuric acid, and then gradually 667 lb. of 30 per cent. solution of sodium bisulphite, after which the sodium sulphate is allowed to crystallise out.

A mixture of chromium sulphite and basic sulphate is prepared in a similar manner, but only 30 lb. of sulphuric acid is employed.

A mixture of chromium sulphite and acetate is prepared by dissolving 112 lb. of sodium bichromate in 100 lb. of water, and 367 lb. of 25 per cent. acetic acid, and then gradually 534 lb. of 30 per cent. sodium bisulphite solution, after which the sodium sulphate is allowed to crystallise out.

The mixture of chromium acetate, sulphite, and sulphate is prepared by replacing part of the acetic acid employed in the last recipe by an equivalent of sulphuric acid, and a mixture of chromium basic sulphate, acetate, and sulphite is prepared by reducing the amount of acetic acid which is employed in the preparation of the mixture of sulphate, sulphite, and acetate.—J. W. L.

Improvements in the Method of and Apparatus for Manufacturing Inlaid Linoleums or Floor Cloths. W. G. Thomson, Halifax, and J. S. Powell, London. Eng. Pat. 4240, March 10, 1891.

A PATTERN block, constructed with one or more chambers of the various shapes required for the pattern, and of any convenient size, is surmounted by a plate carrying cores corresponding in size and shape with those of the chambers in the block. The block is filled with the "ingredients in the various colours required," and placed on the canvas to be printed, and the cores forced down; the block is then raised a little in order to leave a sufficient thickness "of material" on the canvas, a baud-knife being passed under it to detach the protruding colour-mixture. After thus printing, the block is mechanically raised and moved laterally to print a further portion of the canvas, which remains stationary, until all of it on the machine-frame has been printed. The mechanical details of the apparatus employed and several modifications of the above method of printing are described in the original specification, which is illustrated with three sheets of drawings.—E. B.

An Improvement in Dyeing Mats, Carpets, or other Fabrics of Fibre, Wool, Yarn, Silk, or any other Material. J. Daw, jun., North Dulwich. Eng. Pat. 6294, April 13, 1891.

THE object of this invention is to produce ornamental designs or colours on mats or other similar articles without the use of differently coloured materials in the weaving process. For this purpose the mat is placed under a metal stencil plate, and pressure being applied, the colour solution in the form of spray is brought into intimate contact with the material at a considerable temperature and pressure by means of a jet of steam.—W. M. G.

Improvements in the Manufacture of Coloured Rubber Goods or Rubber-coated Goods and a Material or Preparation to be used in the said Manufacture. C. Dreyfus, Clayton. Eng. Pat. 17,566, October 14, 1891.

Improvements in and Means for Dyeing, Mordanting, or Bleaching Textile Fibres. F. Hughes, London. From A. Tebueghin, Gand, Belgium. Eng. Pat. 20,866, November 30, 1891.

THE principal application of the invention consists in an improvement of the ordinary "jigger" machine for cloth dyeing. The latter is constructed either with or without squeezing rollers, both systems having certain defects.

If the cloth is not submitted to a squeezing a good deal of liquor is carried over from one bath to another (say from mordant-bath to dye-bath), and there is consequently a great waste of mordant in the liquor carried forward, and of dyestuff through precipitation by the mordant; there is also a superficial deposition of unfixed dyestuff, which afterwards causes the defect of "rubbing off."

On the other hand, when squeezing rollers are employed in the ordinary way, the dyeing is apt to be irregular from the fact that the cloth is drawn through the liquor at an increasing speed as the diameter of the winding roller gradually increases by the rolling up of the material upon it. In some machines this defect is overcome by driving the winding roller by surface contact with the drawing off roller, but this arrangement is open to the objection that the pressure becomes greater as the weight of the cloth upon the winding roller increases. Thus, in ordinary jigger either the speed at which the cloth travels or the pressure to which it is subjected, is variable.

The inventor claims to have overcome these difficulties in a very simple manner. The improvement consisting solely in so fixing the top squeezing roller that it is easily raised out of contact with the bottom roller, and thus the improved jigger can either be used as an ordinary machine or with the squeezing rollers. The squeezing action depending entirely upon the dead weight of the top roller, is also of necessity constant. An equal speed of travel of the cloth is ensured by driving the winding roller by surface contact with the bottom squeezing roller.—W. M. G.

An Improved Process and Apparatus for Bleaching Paper Pulp and other similar Vegetable Substances. C. Kellner, Manchester. Eng. Pat. 22,437, December 23, 1891.

THE inventor has devised a novel apparatus for the continuous bleaching of paper pulp by means of chlorine gas, the material passing slowly in one direction and the bleaching agent continuously traversing the apparatus in the opposite direction.

The diagram clearly illustrates the construction of the apparatus, the tower A being built up of a series of (preferably) earthenware troughs which divide the structure into a number of compartments. Each trough is provided with one radial opening or slit, and the troughs are so arranged with respect to each other that the slots form an ascending or descending spiral, as shown in Fig. 2. The upper edge of each trough is provided with a gutter, into which the lower edge of the succeeding one is fitted and made gas-tight by a water-seal as indicated in Fig. 3.

Passing through a central hole in each trough is a perpendicular rotating shaft fitted with radial arms, one in each compartment (*a*, Fig. 1).

The paper pulp is fed into the apparatus through the hopper *k* and falls to the bottom of the first compartment; it is there pushed round by the radial arm until it reaches the slit through which it falls on to the next trough; proceeding in this manner until it reaches the bottom of the apparatus. Chlorine gas is meanwhile passing in the opposite direction, entering by the pipe *h* and finding exit at *i*. The height of the tower and the rate of supply of chlorine must be such that the pulp is thoroughly bleached, but no excess of chlorine escapes at *i*.

IMPROVED BLEACHING APPARATUS.

The hydrochloric acid produced in the bleaching operation is recovered and again used for the production of chlorine by the electrolytic method.—W. M. G.

VII.—ACIDS, ALKALIS, AND SALTS.

Variations in the Specific Gravity of Nitric Acid produced by Nitrogen Peroxide. G. Lunge and L. Marchlewski. Zeits. f. angew. Chem. 1892, 10—12.

Pure nitric acid of commerce, sp. gr. 1.4960 at 15° was mixed with different quantities of pure nitrogen peroxide, prepared by heating lead nitrate. The specific gravities were taken with a hydrometer at 15° , 17° , 19° , and 21° , with the following mean results:—

Percentage of		Specific Gravity at 15° in Vacuum.	Variation in Specific Gravity for each Degree of Temperature.
Nitrogen Peroxide.	Nitric Acid (Total Acidity).		
1	1.04	93.25	1.4986
2	2.93	93.37	1.5071
3	5.82	94.35	1.5129
4	7.32	95.09	1.5261
5	12.70	97.77	1.5415

To estimate the nitrogen peroxide the acid is charged into an accurately calibrated narrow burette, divided into $\frac{1}{100}$ cc., and which can be read to $\frac{1}{1000}$ cc., and allowed to assume the temperature of the room. It is then run gradually into a known volume of semi-normal permanganate heated to 40° , until the colour is discharged, the quantity of nitrogen peroxide being then readily calculated. The total acid was ascertained by running 16 cc. of the acid from the above burette (thus avoiding the inconveniences attached to weighing such material) into ice-cold water, making up to 100 and titrating, whilst warming an aliquot part. Litmus was used as an indicator. By considering the above numbers in various ways the following data are obtained, which show

	A.	B.	C.	Specific Gravity of Acid B.	Specific Gravity of Acid C.	Variation of Specific Gravity for each 1 per Cent. of N_2O_4 .
—	Nitric Acid corresponding to the Nitric Peroxide present.	Actual Nitric Acid less that due to Nitric Peroxide.	Actual Nitric Acid with half that due to the Peroxide.			
	Per Cent.	Per Cent.	Per Cent.			
1	1.42	91.83	92.54	1.4954	1.4969	0.00317
2	4.02	89.55	91.56	1.4899	1.4950	0.00599
3	7.97	87.58	90.56	1.4816	1.4924	0.00658
4	10.32	84.77	89.93	1.4760	1.4909	0.00693
5	17.40	80.37	89.07	1.4613	1.4886	0.00654

the relationship of the specific gravity to the amount of nitric peroxide present, and as this is not regular the authors noted down all results obtained, and struck a mean curve from which they have constructed the following table, to show the variations of specific gravity of the strongest acid of commerce under the influence of the presence of nitric peroxide. The experiments with weaker acids have not given satisfactory numbers.

VARIATIONS IN THE SPECIFIC GRAVITY OF NITRIC ACID, Sp. Gr. 1.4960 at 15° IN VACUO BY THE ADMIXTURE OF NITRIC PEROXIDE.

4.25	0.02680	8.75	0.05825		
4.50	0.02875	9.00	0.06000		

The nitric peroxide is regarded as all inactive in the above table, inasmuch as the authors consider that the reaction, $N_2O_4 + H_2O = HNO_3 + HNO_2$, may be disregarded when using such strong acid, but if it is to be taken into consideration, a smaller number than those above given would have to be deducted from the numbers given in Lunge and Rey's tables (this Journal, 1891, 544-546), in order to ascertain the actual amount of active nitric acid and a special table would have to be constructed.—D. A. L.

PATENTS.

Improvements in the Treatment of Soda Waste. F. Ellerhausen, Heliurn-on-Tyne. Eng. Pat. 20,012, December 8, 1890.

Waste, consisting principally of sulphide of iron and sodium is treated either in the wet condition in a closed vessel with carbonic anhydride or in the dry state in a muffle furnace. If the treatment takes place in the wet state hydrogen sulphide is expelled, whilst in the furnace the sulphur passes off as sulphurous anhydride. In any case the resulting mixture of sodium carbonate and ferric oxide is heated until sodium ferrate is formed.—J. W. L.

Improvements in the Manufacture or Production of Salt from Brine. E. O. Lambert, London. From S. Pick, Szczakowa, Galicia. Eng. Pat. 1453, January 27, 1891.

The invention has for its object the precipitation of salt from brine by treatment of the brine with solution of substances having a strong affinity for water, such as the chlorides of calcium and magnesium. The quantity and quality of salt precipitated from brine depends upon the strength and quality of the precipitating solution employed. By adding two volumes of chloride of calcium solution, having a specific gravity of 80° Tw. to one volume of brine, about 98 per cent. of the salt may be separated from the brine in the form of flour salt. By mixing one volume of chloride of calcium solution with 2 volumes of brine, only 25 per cent. of salt are precipitated again in the state of flour salt. In the latter case the remaining 75 per cent. may be obtained either as ordinary fine salt (table salt) or as coarse salt. In the first case the liquor is concentrated to a point at which salt begins to precipitate. On cooling, the salt crystallises out, it being more soluble in hot than in cold solutions of chloride of calcium. The mother-liquor may be repeatedly concentrated and cooled until it consists practically of chloride of calcium only. By varying the quantity of calcium chloride liquor employed in the first instance, and also the subsequent treatment of the mother-liquors, the different grades of salt may be obtained in any required proportion. In all cases the salt obtained is washed by brine in filters or other suitable vessels, and salt is produced from such water in the same way as described. Detailed drawings of an apparatus suitable for the production of salt in the above manner accompany the specification (this Journal, 1888, 426; 1890, 616; 1891, 624 and 749).

—K. E. M.

A New or Improved Method of Manufacture of certain Compounds of Chromium used in Dyeing and Calico Printing. W. Watson and E. Bentz, Manchester. Eng. Pat. 3385, February 24, 1891.

See under VI., page 430.

Improvements in the Production of Chlorine. F. M. Lyte, London. Eng. Pat. 4068, March 6, 1891.

PLUMBIC chloride is first formed from either native or waste chlorides, such as sodium chloride, hydrochloric acid, calcium chloride, magnesium chloride. From these chlorides hydrochloric acid is first formed, either by the Le Blanc, or Lyte and Steinhart's processes, and it is then treated with plumbic oxide, acetate, or nitrate.

Ammonium chloride may be boiled with plumbic oxide. The plumbic chloride thus obtained is melted in a trough or crucible of either earthenware or enamelled iron, and a current of electricity of low tension, about 5 volts, is passed

through it, the poles being either of carbons, or carbons form one pole, the anode, and molten lead, previously added, forms the cathode, the connection with the latter being made by means of a tinned iron bar passed through the bottom of the vessel.

The molten lead is allowed to pass away, as it is formed, through a syphon which maintains a constant level in the trough.—J. W. L.

Improvements in the Manufacture of Alkali and Apparatus therefor. W. Mills, London. Eng. Pat. 4661, March 16, 1891.

THE invention refers to the treatment of fused sodium chloride with a mixture of about equal volumes of hydrogen and carbonic oxide, such as water-gas, in shallow iron pans, Bessemer converters, or reverberatory furnaces. The gas is passed into the fused mass by means of perforated pipes. As a result of the reaction, "hydrochloric acid is given off, and a mixture of sodic oxide and carbon remains behind." This residue is available for the production of caustic soda, by lixiviating, filtering off the carbon, and evaporating the solution. The carbon may be otherwise eliminated by passing a blast of air through the melted mass, when "sodic oxide" will remain behind "in a pure state."—H. A.

Improvements in or Appertaining to the Manufacture of Alkali. A. G. Haddock, Ditton, and J. Leith, St. Helens. Eng. Pat. 5844, April 4, 1891.

IN a previously patented process (this Journal, 1891, 641) residues of alkali waste and of gypsum are obtained, both containing a certain proportion of sulph-hydrates. It is proposed to eliminate these by washing with water, decanting, and treating the remaining thick cream with carbonic acid, which is afterwards passed into the carbonators.

It is important for many processes in using carbonic acid to obtain the same free from oxygen. This end may be attained by adding to it water-gas, hydrogen, or hydrocarbons, either in the lime kilns or in other externally heated apparatus,—the oxygen being consumed in the combustion of these compounds.—H. A.

Improvements in Treating Waste Liquor from Galvanising Works and other Similar Liquors to obtain Ferric Chloride. J. W. Wilson, Manchester, and C. H. G. Harvey, London. Eng. Pat. 6509, April 16, 1891.

THE waste liquor is fed in from a suitable reverberatory furnace, which is provided with flues for carrying away the acid fumes evolved in the operation. The furnace is heated by means of fuel free from sulphur, in conjunction with an air blast. The liquor evaporating, gradually forms an impervious crust on the furnace bed, and when the crust is of sufficient thickness, the running in of liquor is stopped and the temperature of the residue on the furnace bed raised to a bright red heat. As ferrous chloride is converted into ferric chloride the latter is volatilised, and the vapours are condensed in tanks containing hydrochloric acid. The residue of ferric chloride and ferric oxide is introduced while hot into the same hydrochloric acid tanks, the contents of which may be heated to the boiling point. The whole of the iron is thus converted into a supersaturated solution of ferric chloride. The gaseous hydrochloric acid given off in the process, is condensed in suitable apparatus and may be used over again.—H. A.

A Process for Recovery of Sulphur, Carbonate of Soda, and Iron Oxide from Double Sulphide of Sodium and Iron. G. Lunge, Zürich, Switzerland, and J. Dewar, London. Eng. Pat. 8018, May 9, 1891.

IN a process for the production of caustic soda (this Journal, 1891, 543 and 547) a residue is left "consisting mostly of a double sulphide of sodium and iron, or it may be of several such double sulphides, the composition of

which is not exactly known." The moist residue, when exposed at ordinary temperatures to the action of a mixture of, say, one vol. of carbonic acid to about four vols. of air, decomposes with formation of sodium carbonate and of certain quantities of sodium hyposulphite, both of which may be extracted by lixiviation. The insoluble matter consists of hydrated sesquioxide of iron, sulphur, and a quantity of "special double sulphide or of sulphides of sodium and iron;" the amount of these latter depends on the length of time for which the process has been carried on. The sulphur may be melted out, burnt out, or extracted by means of carbon bisulphide, and the residue may be used over again for the manufacture of sodium ferrite, whilst the soluble sodium salts are utilised for the production of ash, caustic, or sodium ferrite.—H. A.

A Method of Manufacturing and Regenerating Salts of Peroxide of Iron. A. E. M. L. Paillard, Paris, France. Eng. Pat. 8841, May 25, 1891.

When reduced to ferrous salt in some technical oxidising process, it is proposed to regenerate the persalts for further useful oxidising action, by treatment of the ferrous salt in solution with the necessary amount of sulphuric acid and a small quantity of nitric acid, for conversion into sesquisulphate. The mixture is then blown by means of an injector into a receiver, where the separation of the liquid and the gases takes place. The latter are returned with an admixture of air to an absorbing chamber connected with the suction of the injector for the regeneration, to a certain extent, of the nitric acid.—H. A.

Improvements in and Apparatus for the Concentration of Sulphuric Acid. J. L. Kessler, Clermont-Ferrand, France. Eng. Pat. 19,215, November 6, 1891.

The apparatus consists of a series of shallow evaporating pans made of siliceous materials covered with lead, and the figure represents a vertical section of one form of it. The heat is derived from a large open fire of slow draught, and after putting on fresh fuel the draught must be cut off from the apparatus in order to prevent the acid from becoming contaminated with dust. The hot air is preferably drawn through the apparatus by means of an exhaust at the outlet. The temperature of the acid need not rise above 203°.

The apparatus consists of the trough S into which the hot gases pass from the furnace. They circulate first through the passages $q\ q$ ($q^2\ q^2$ are partitions) from which it passes to the passages $q^1\ q^1$, and the acid is readily concentrated

APPARATUS FOR CONCENTRATING SULPHURIC ACID.

to 66° B. in this trough. The gases pass upwards over each succeeding trough of acid, whilst from the upper troughs the acid flows downwards, finally reaching the bottom trough S. The weak acid to be concentrated is run into the uppermost trough and becomes gradually concentrated as it passes to the lower ones.—J. W. L.

Improvements in the Manufacture of Sodium Borates.

C. Bigot and J. Schreiter, Hamburg, Germany. Eng. Pat. 19,382, November 9, 1891.

CALCIUM borates may be converted into calcium tetraborate by treating them with sulphuric acid or sodium hydrogen sulphate, and the calcium tetraborate may be readily converted into sodium tetraborate by heating with sodium sulphate. The quantities recommended are: 100 parts of calcium borate, 200 parts of water boiled with 37 parts of sulphuric acid and 140 parts of sodium sulphate, or with 91 parts of sodium bisulphate and 85 parts of sodium sulphate. The mixture may be boiled under a pressure of 2½ atmospheres or in an open pan fitted with an agitator. The gypsum is then filtered off, and sodium baborate, borax, obtained from the solution of sodium tetraborate by the addition of lime or soda.

—J. W. L.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

PATENTS.

Improvements relating to Ovens, Kilns, or Furnaces for Firing Pottery or Earthenware, and for other Purposes.

F. Plant, Stoke-on-Trent. Eng. Pat. 4610, March 14, 1891.

In order to retard the passage of heat through the flues, "obstructers" made of fireclay or other refractory material having perforations or openings for the passage of the products of combustion are placed in or upon the outlets of the flues of the ovens. They are preferably circular or arch-shaped to prevent them collapsing owing to the high heat to which they are exposed.

In a pottery oven they may be placed on the top of the "bags" and also at one or more points in the well hole.

Along with these "obstructers" perforated laps or covers may be used, the combination forming chambers through which the heat and smoke pass to assist in the combustion. Steam or air is in some cases introduced into the chambers.

A dome-shaped cover is also described which may be placed on top of the oven and be raised when required by a lever or other suitable means.

There are two sheets of drawings showing ovens fitted with obstructers and covers.—D. A. S.

Improvements in, and in the Preparation or Manufacture of Enamelled Iron and Steel Plates and other Enamelled Iron and Steel Ware, having Letters, Figures, or Designs appearing at or in the Surface thereof. C. F. Clark, Wolverhampton. Eng. Pat. 4853, March 18, 1891.

HITHERTO letters, designs, &c. have been produced on iron and steel plates by first coating the whole surface with a coloured opaque enamel, and then forming the letters or designs of another enamel on the surface of the first enamel. Another method was to form the letters in opaque enamel on the surface of the metal plate and then to coat the general surface nearly or quite to the level of the raised letters.

In this invention letters or designs *sunk* in the metal plate are filled with opaque enamel, and after burning or baking a transparent or semi-transparent enamel is spread over the surface of the plate, and also over the opaque enamel.—V. C.

Improvements in Kilns for Use in the Manufacture of Pottery, Porcelain, and Earthenware and other similar Goods. F. Query, Montgesoye, France. Eng. Pat. 5068, March 21, 1891.

EACH of these kilns consists of three portions, the kiln proper, a regenerator situated below the kiln, and a drying stove for drying the articles to be afterwards fired in the kiln. When intended for use in making enamelled or glazed ware a supplementary laboratory or kiln body is used.

The waste gases from the kiln after passing through the regenerator are used for heating the drying stove. The air for combustion is admitted through the regenerator and so heated. A special feature of the furnace is its construction, enabling short bars of refractory material to be used, thus dispensing with grate-bars of cast metal, which effects considerable economy in the firing of glazed stoneware.

The inventor claims by the use of this kiln to effect saving in cost of fuel, fire-bars, and drying, while securing increased production from a number of kilns, as also great regularity in heating and cooling.

By means of such a kiln a charge of wares may be charged, fired, and discharged "in 72 hours at the most." The specification is illustrated with drawings.—D. A. S.

Improvements in the Manufacture of Terra Cotta Ware. W. S. Edwards, Ruabon, and J. W. Edwards, Wrexham. Eng. Pat. 17,384, October 13, 1891.

DURING evaporation of the mixture a "scum" or light-coloured substance is apt to form on the surface of terra cotta. The processes in use for removing this blemish (e.g., by scrubbing) are injurious, because they leave the surface rougher.

This invention aims at preventing the formation of a "scum" by coating the surface of the terra cotta with hot tar. Those surfaces which will not be exposed to view are left uncoated, and through them only evaporation takes place.—V. C.

Improvements relating to the Enamelling of Iron Plate. H. Claus, Thale in the Harz, Germany. Eng. Pat. 22,705, December 29, 1891.

IN order to enamel iron-plate utensils in imitation of granite or in mottled or variegated colours, and with a rough surface, the articles undergo three treatments.

They are coated first with an enamelled ground and then washed with a solution of magnesium and ammonium sulphates, which serve to decompose the next enamel coating. This second enamel is very coarsely ground to produce roughness. A thin paste of transparent enamel as finely ground as possible is finally applied.—D. A. S.

Improvements in the Production of Enamelled Iron Ware. H. Claus, Thale in the Harz, Germany. Eng. Pat. 22,732, December 29, 1891.

IN order to obtain mottled enamelled iron ware in grey, blue, or white marbling or other tints one of two processes may be used, either the iron receives a single thick coating or two or more thin coatings. For the former process the enamels are such that the metallic ground work may be partially oxidised and speckles produced in the enamel. The alkaline ingredients are reduced so as to obtain a completely glazed hard mass after melting down. In the second process the ground enamel is of elastic soft composition, and may be mixed with nickel or cobalt oxide; it should be applied in a very thin layer. The covering material consists of finely powdered felspar, granite, sand, cryolite, borax, saltpetre, kaolin, and tin oxide; when these are ground to a mass some nickel sulphate and cobalt sulphate are added. The mixture is then applied in thin layer, and while still moist is powdered over with some ammonia soda (sie) dried and fired as usual. The glaze is alleged to be beautifully tinted.

The inventor explains the reaction as due to the formation of NiCO_3 and CoCO_3 on addition of the soda; these substances tending to draw out and absorb the dissolved NiSO_4 and CoSO_4 to form basic salts, $2\text{CoCO}_3 + 3\text{Co(OH)}_2$ or $2\text{NiCO}_3 + 3\text{Ni(OH)}_2$, thus the colouring matter is concentrated at central points. On the addition of the soda, sodium sulphate is formed, this quickly takes up water of crystallisation causing currents in the enamel and producing beautiful designs.

These enamels are of great durability and resist acid. For the resistance of strong chemical reagents a thin covering of felspar, fluorspar, quartz, borax, and saltpetre is applied.

Salts of copper, chromium, iron and manganese may be used.—D. A. S.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Hydraulic Mortars from Slag. M. Müller. Zeits. f. angew. Chem. 1892, 196—110.

IT is well known that the basic slag resulting in the manufacture of grey pig iron has the property of hardening under water when mixed with calcium hydrate. Mixtures of such slag and calcium hydrate are extensively produced and used as Puzzolana cement: the proportion in which the ingredients are mixed being 3 parts of slag meal and 1 part of calcium hydrate, which latter may be substituted by Roman cement. The ironmasters themselves do not manufacture the cement, but they occasionally prepare stones from the slag, thus deriving sometimes larger profits from the by-product than from the pig made. For this purpose the slag, in the form of a coarse powder, is mixed with calcium hydrate in the proportion of 4:1, the mass shaped into stones and allowed to remain in the open air in a moist state until they have attained the required hardness. The great weight of these stones naturally localises such a trade.

Only those slags are suitable for the manufacture of the Puzzolana cement which result from grey pig made in blast furnaces, the slags from white iron, spiegel, &c. being completely unsuitable for this purpose. But this property of the slag to form a hydraulic cement does not depend solely on its chemical composition; only on the condition that the molten slag, just as it is flowing from the tap hole of the blast-furnace, is suddenly chilled by being run in a thin stream into water, will it be found suitable for the manufacture of Puzzolana cement. Through this operation the slag is disintegrated at the same time to a great extent, and can, after drying, be easily reduced to the finest meal by being ground between crushers.

If the slag be not chilled, but allowed to cool slowly, the powdered slag will not harden under water when mixed with lime, although the chemical composition is exactly the same.

The strongly basic slags have the property of swelling out in contact with air, and thus becoming disintegrated into a very fine powder; but this slag cannot give a hydraulic cement either.

The different behaviour of chilled and naturally disintegrated slag is therefore not caused by a change in its chemical composition, but by an alteration in its chemical constitution. In the chilling process, the chemical compounds, as they exist in the molten slag, are, so to speak, fixed, while, on slowly cooling, a change in the grouping of the atoms must take place. It is, therefore, evident that the molecules of the slag are under a certain tension, and thus enabled to easily form new compounds when mixed with other substances. The author had tried, some years ago, to define the chemical difference, but did not arrive at any tangible result, therefore he did not publish his work. A communication, however, of A. Busch (this

Journal, 1892, 165) induces the author to communicate the results of his researches. Busch concludes from the action of bromine water on the slag which has crumbled to pieces on contact with air, that such slag contains large quantities of free, dead-burnt lime, and that the chilled slag also occludes some such lime, wherefore these cements do not harden in contact with sea-water. The residue left from the action of bromine water on the slag is considered by Busch to have the formula $Al_2O_3(SiO_2CaO)_2$. The author attacks these conclusions of Busch as not consistent with the facts.

The material for a comparative examination of chilled slag and slag disintegrated by contact with air, not being easy to obtain, the author proceeded to prepare the latter from a chilled slag in the laboratory by heating the chilled slag in a muffle to a bright red heat, and allowing it to cool slowly. In consequence of this heating, the chilled slag loses altogether the property of yielding a hydraulic cement, whilst its chemical composition has undergone only slight alteration, the calcium sulphide contained in the chilled slag becomes oxidised through the heating in the muffle to calcium sulphate. The specific gravity, however, is considerably lowered owing to the increase in volume. The analyses of the original chilled and of the heated slag gave the following results:—

	Chilled Slag.	Heated Slag.
	Per Cent.	Per Cent.
SiO ₂	25.63	25.41
Al ₂ O ₃ (+ Fe ₂ O ₃).....	18.81	18.61
CaO.....	50.82	50.62
MgO.....	3.15	3.05
Specific Gravity.....	2.710	2.413

The action of bromine water on both slags was determined by allowing the finely-powdered slags to stand for a fortnight in a well-stoppered bottle with an excess of bromine water, and examining the filtrate from the undissolved portion. The analysis yielded the following values:—

Dissolved in Bromine Water in 14 Days.	Chilled Slag.	Heated Slag.
	Per Cent.	Per Cent.
SiO ₂	0.45	0.93
Al ₂ O ₃ (+ Fe ₂ O ₃).....	0.2	0.19
CaO.....	13.5	33.50
MgO.....	Not determined.	

When the bromine water is allowed to act for a longer period, the chilled slag loses considerably more lime, whilst the heated slag undergoes very little further change, as the author proved in another specimen of slag.

From these experiments the author concludes that the lime of disintegrated furnace slag is more loosely combined than in the chilled slag, but it would be premature to conclude, as Busch does, that this lime is dead-burnt lime, which, in contact with sea-water, forms calcium sulphate and magnesium hydrate, thus causing the uselessness of the Puzzolana cement for building purposes under sea-water. If Busch's opinion be correct, Portland cement, which withstands the action of sea-water well, ought not to contain free lime, and consequently not yield any lime to bromine water. The author examined, therefore, a good Portland cement (Stettin Star brand) containing 64.44 per cent. CaO, and found that bromine water dissolved from it during a fortnight the greatest part of the CaO; in fact 89.7 per cent. of the lime present in the Portland cement was found in the solution. As no one would contend that such a large percentage of free lime exists in Portland cement, it will be considered more likely that there is

present in it a chemical compound containing large quantities of CaO, which hardens easily by combining with water, but is easily decomposed by bromine water.

Experiments of the author to extract free lime from both the chilled and the heated slags by means of a 20 per cent. sugar solution showed that only very small quantities of CaO were dissolved.

It is generally assumed that the slag only hardens on addition of lime. The author concludes from his experiments that the slag meal itself takes up water slowly, thereby becoming hardened.

Chilled slag and heated slag were kept in test tubes under water for a period of five weeks, when the chilled slag was found to have become quite hard, whilst the heated slag could easily be crushed with the finger. The author determined the amount of water taken up by drying the samples in a desiccator and weighing the water given off on subsequent heating. He found, for the chilled slag, 7.15 per cent. water, and for the heated slag 3.55 per cent. Another experiment, extending over a period of three months, gave for the chilled slag 10.71 per cent., and for the heated slag 5.41 per cent. water.—J. L.

PATENTS.

Improvements in and in the Preparation or Manufacture of Enamelled Iron and Steel Plates and other Enamelled Iron and Steel Ware having Letters, Figures, or Designs appearing at or in the Surface thereof. C. F. Clark, Wolverhampton. Eng. Pat. 4853, March 18, 1891.

Improvements in Clay Presses for making Tiles and the like. C. Huelser, London. From E. Fröhlich, Schwerin, Germany. Eng. Pat. 5772, April 3, 1891.

A DEVICE for quickly forming tiles, &c., by means of clay presses.

The mould box B is secured to the mouthpiece of the

AN IMPROVEMENT IN CLAY PRESSES.

clay press, the box being provided with core pieces D, a stencil C which can be taken out, and slits i for allowing the air to escape. When the clay begins to come out through these slits the lever nut k is loosened and a wire is passed along the rear of the mould box b, whereby the tile O is formed.—V. C.

An Improved Artificial Stone. W. W. Horn, London. From W. L. Mason, T. W. Blakey, and J. A. Wright, Keene, U.S.A. Eng. Pat. 7184, April 25, 1891.

The material is made from the following ingredients: granite 40 parts, flint 15, felspar 5, fireclay 4. The granite is calcined and afterwards pulverised and sifted. The other materials in the proportions above stated are thoroughly mixed with the granulated granite and water. The mixture

is then moulded, set aside to dry, placed in saggars, and heated to about 4,000° F. The material obtained resembles granite but is stronger, is fireproof, and is practically impervious to water.—V. C.

Improved Fire-Resisting Bricks and Materials for Lining, Facing, or Coating Fire-places, Fire-boxes, Ovens, and Kilns of every kind. J. K. Thompson, Leeds. Eng. Pat. 21,997, December 16, 1891.

THE material consists of a mixture of 7 parts of ground fireclay, 1 part of graphite, 1 part of plumbago, 1 part of cement and the necessary water. When bricks are to be made the materials are moulded and subjected to hydraulic pressure, after which they are fired in the usual way.

The same mixture, but made more fluid by an additional quantity of water, can be used as a wash or coating for ordinary fire-bricks or other articles.—V. C.

Improvements relating to the Enamelling of Iron Plate. H. Claus, Thale, in the Hartz, Germany. Eng. Pat. 22,705, December 29, 1891.

Improvements in the Production of Enamelled Iron Ware. H. Claus, Thale, in the Hartz, Germany. Eng. Pat. 22,732, December 29, 1891.

See under VIII., page 435.

Improvements in Gypsum Casts. E. Websky, Tannhausen, Germany. Eng. Pat. 795, January 14, 1892.

THE inventor's object of rendering gypsum casts capable of withstanding exposure to the atmosphere, of improving their artistical appearance, and allowing their being easily cleaned, is attained by immersing the dried casts, previously heated to a temperature of 170°–200° F., into a drying oil having the same temperature. After 8 or 10 hours the gypsum casts are taken out and allowed to stand 12 hours in a place free from dust. The same process is repeated once more for a shorter period of time, the adhering oil is carefully removed and the casts again allowed to dry.

The gypsum casts are thus rendered translucent to a certain depth and acquire a stone-like appearance.

The oil used is bleached linseed oil (or red poppy oil, hemp oil, nut oil, castor oil) with or without an addition of 10–20 per cent. of Dammara resin. It is not advisable to accelerate the drying of the oil by adding a dryer.—J. L.

Canadian Nickel. Board of Trade Journal.

IN an article on Canadian nickel production, the *Monetary Times* of Toronto says that the nickel deposits at Sudbury, Ontario, form one of the two great sources of the world's supply of this metal, the other being the mines of New Caledonia, a colony of France situated in the Pacific Ocean, some hundreds of miles east of Australia.

The great deposits in New Caledonia are of garnierite, a hydrous silicate of nickel and magnesia, while the Sudbury ores are of nickeliferous pyrrhotite and chalcopyrite. The quantity of nickel mined in the United States in the last 16 years, according to a paper on nickel by Mr. W. R. Ingalls, M.E., has averaged only 121,000 lb. per annum. The principal source of the metal in that country is the Lancaster Gap, Pennsylvania mine, but its output is lessening, and in fact it shows signs of exhaustion. There are other deposits of the nickel in Nevada, Arkansas, Oregon, North Carolina, and Connecticut, as well as in the Black Hills of South Dakota, but none of these mines, we understand, have yet become regular producers. The deposits vary in character from a cobalt and nickel sulphide, as at Churchill, Nevada, to the nickel silicate found at Riddles, Oregon. Exports of nickel from the New Caledonia mines reached 885,000 lb. in 1890, nine-tenths or more in the form of nickel ore averaging 8 per cent. of the metal. Norway produced in 1889 some 149,000 lb. Says Mr. Ingalls:—

"The nickeliferous chalcopyrite and pyrrhotite of Sudbury are first roasted and then smelted in cupola furnaces to nickel-copper matte, containing about 20 per cent. nickel. These mattes are very refractory, and it is only within the past year that they have been successfully handled. Of the large output in the Sudbury district in 1890 but a comparatively small portion was shipped. About 15 months ago the Orford Copper Company devised a successful method for refining these mattes, and since then the bulk of the output of the Canadian mines has been brought to this country, the Orford Copper Company now being the largest nickel refiner in the world. Early in the year the United States Government purchased a large amount of matte of the Canadian companies, practically cleaning out their accumulated stocks, and all of this has been refined by the Orford Company. By the process used by the latter, which is a secret one, the copper and nickel in the matte are separated and the nickel converted into nickel oxide, which is said to be more suitable for the manufacture of nickel steel than metallic metal. A small part of the Sudbury mattes is sent to Swansea to be refined."

Of the three nickel smelting works in the United States, the American works at Camden, N.J., run on Pennsylvania, Missouri, and Canadian ores; the Orford works, opposite Staten Island in New York harbour, on Canadian mattes only; while the Canadian Copper Company's works at Cleveland, Ohio, are to run, when completed, upon mattes from that company's mines at Sudbury. La Société du Nickel, which owns the New Caledonia mines, has four refineries in operation; one near Havre, in France; one at Eiserohn, in Germany; one at Glasgow, Scotland; one at Irdlington, near Birmingham, England.

Matters in the Canadian nickel belt in northern Ontario, about Sudbury, are by no means stationary. We hear that the Drury Nickel Company, whose lands are in the township of Drury, have not only built a smelter which is about ready for work, but have constructed a line of railway to connect their property with the Canadian Pacific Railway.

A late paragraph mentions the formation at Havre of a company for the manufacture of nickel, which shall use the mineral from Canadian mines. This points to competition with La Société du Nickel, which controls the New Caledonia mines. At any rate this new company is erecting a factory on the Tancarville canal at Havre, and is said to have concluded an important contract with the Government of France for nickel-plating parts of the Lebel rifles.

On the Oxidation of Nickel Carbonyl. Berthelot. *Compt. Rend.* 1891, **113**, 679—680.

THE author has already described several new properties of nickel carbonyl, and showed that it behaves as a true organic radicle, the products of its spontaneous oxidation not consisting simply of oxide of nickel and carbonic acid. New details are now given.

Nickel carbonyl may be preserved without alteration in a flask under a layer of water, so long as air is absolutely excluded. If the air penetrates into the flask the compound is slowly oxidised, forming at the bottom a stratum of apple-green hydrated oxide of nickel (free from carbon in the author's experiments). At the same time some of the nickel carbonyl escapes and is oxidised by the air, forming fumes which deposit as a whitish film upon all objects in the same cupboard.

In order to collect this product of slow oxidation the flask was placed in a double tin jacket, and in this way several decigrammes of a complex oxide were collected. This body, which is whitish in film but greenish in bulk, is a hydrated oxide of an organic radicle compound of nickel.

Its analysis by oxide of copper gave numbers approximately corresponding to the formula $C_2O_3 \cdot Ni_3 \cdot 10 H_2O$.

It is the oxide of a complex radicle analogous to croconic or rhodizonic acid, and a part of the nickel may be combined or mixed with it as a simple oxide. In this case the complex oxide would be some such substance as C_2ONi , and would be derived from ethylene (C_2H_4) or a more condensed type of the same series.

The equation representing its formation would then be— $C_2O_4Ni + O = 2 CO_2 + C_2ONi$.

Further study of nickel carbonyl is necessary to prove this.—W. M. G.

Formation and Behaviour of Basic Calcium Phosphates, and their Relationship to Thomas Slag. O. Foerster. *Zeits. f. angew. Chem.* 1892, 13—22.

The Condition of Gold in Pyrites. Eng. and Mining J. 1892, 151.

TREATISES on ore deposits frequently refer to the occurrence of gold in the form of a natural sulphide as possible and probable. There is really foundation for the belief that gold often does occur in a state which resists amalgamation, even with the best mechanical appliances.

While the theory of the existence of a gold sulphide meets with no objections, and is assumed as a convenient working hypothesis, to establish it by positive proof is another and by no means an easy matter. A sulphide ore (pyrites, arsenopyrites, chalcopyrites, marcasite, blende, galena, &c., a mixture of two or more of these, or of silver sulphides, perhaps in connexion with arsenides, antimonides or tellurides) which carries 10 oz. to 20 oz. gold per ton, would be of exceptionally high grade. The bulk of the auriferous sulphuret concentrates does not run higher than one or two ounces per ton. And since of this gold a large part, nearly all, or the whole, may be in the metallic state, laboratory experiments become very difficult and their results uncertain, owing to the small percentage of gold (whether native or as sulphide) available to work upon. The same difficulty was met with in determining gold tellurides. If an auriferous pyrites ore is crushed and, without roasting, is panned or horned, a portion of the gold contents (as determined by fire assay) may be recovered, the gold being in various degrees of comminution down to a fineness which may escape the most careful panning. Such a pyrites, examined under the microscope, sometimes shows minute films and flakes of gold lying along the cleavage planes as though squeezed out in the process of crystallising, or in particles in the mass of crystals. Most of the gold-bearing pyrites does not occur in large blocky crystals, but finely disseminated through the quartz, spar, or other gangue, and hence does not lend itself readily to observation.

Some sixteen years ago Mr. W. C. Wynkoop detected what he believed to be a natural sulphide of gold in copper pyrites from the Stoughton mine, Ward district, Boulder county, Colo. This ore was not amalgamable raw, showed no gold nor any signs of an unknown mineral under the microscope, but on treating with ammonium sulphide gave a filtrate containing gold. Recently certain investigations have been described by Mr. T. W. T. Atherton, of the Nambucca Heads Gold Mining Company, of Deep Creek, New South Wales, which seem to be conclusive, if any doubt remains. Mr. Atherton proves that during his investigations on the ores of the Deep Creek mines he has found in them the long-sought gold sulphide.

If natural gold sulphide exists and is not amalgamable, it cannot be reduced by any simple process of grinding, which, however, may liberate some other forms of refractory gold. Roasting would probably drive off the sulphur more easily than from other sulphides, as the gold sulphide, it is to be presumed, is a less stable compound. But roasting would leave the freed gold in such a minute state of subdivision as to make it an awkward material to handle by any amalgamating appliances, since it would be likely to escape in the slimes. Concentration, roasting, chlorinating, and leaching ought to save it, or, perhaps, even a raw lixiviation process may be practicable. At present concentration and smelting after roasting (or raw, if in small proportion in the smelting mixture), in connexion with silver-lead smelting, seems to be the simplest and surest mode of treatment. But fine crushing before concentration would tend to slime the gold sulphide, which most probably exists as an intimate mixture scattered through the base sulphides, as a distinct mineral, perhaps, yet undistinguishable to the eye and not mechanically separable from the other sulphides.

These questions are pertinent: Does much of this gold sulphide really exist, and is its occurrence more frequent than is supposed? If so, will it prove to be of sufficient importance to modify metallurgical methods?

The World's Store of Tin. E. W. Clappole. *Iron*, **39**, 362—363; *Engineering Mag.* January 1892.

CASSITERITE is almost always found associated with primitive rocks, chiefly granite. It never occurs, as does iron, in seams, or in narrow solid veins, as do galena and some other ores, but disseminated in detached, and often very minute, crystals in the vein-stone. The veins may vary from a few inches to many feet in width, and through this mass the ore is dispersed with great irregularity, large parts being absolutely barren, while through others the cassiterite is diffused in shreds, streaks, and patches. This scanty diffusion in the granite or other matrix, and the small extent of workable tin country yet known in the world, are together the causes of the scarcity and high price of the metal in the market. The only countries in which we have any real knowledge of the geology of cassiterite are Spain, Saxony, Britain, and, to a smaller degree, South Dakota. In all the other regions from which tin is obtained, the ore is for the most part picked up on the surface, and not mined below it.

In Cornwall the granite occurs as a number of bosses projecting through the slates which formerly overlay them, but have been removed by erosion. Dartmoor, in Devon, is the largest of these, and they continue in a south-westerly direction through Cornwall and the Scilly Isles, but not all of them are equally stanniferous. The cassiterite in Cornwall occurs in lodes that traverse alike the granite and the slates, and are consequently of later date than both. These lodes run in a direction from west-north-west to east-south-east, and are cut by a series of cross courses running nearly north and south, and often carrying lead, silver, or manganese, but rarely tin. The country is thus cut up into a number of rudely-rectangular blocks, and the points of greatest productiveness, or pockets, are at the intersections of the lodes with the cross courses.

The Cornish tin-stone is not geologically ancient. That tin ore has, however, been formed in other cases at a later date than that above assigned to the lodes is proved by the discovery of deer-horns so thoroughly impregnated with cassiterite that they were as rich in tin as the average ore of

the county. The lodes of tin ore not unfrequently split up into fine thread-like veins which so penetrate the slate that both must be worked together.

The story of the Dakota tin is very different. There the cassiterite is confined strictly to the granite. But the granite is not a vast erupted mass as is that of Cornwall. It is probably a result of aqueo-thermal action. There is a wonderful similarity between the ores of the two places, indicating similar condition of formation. The tin-bearing lodes are for the most part on the western side of the Black Hills, among the older schists, and are of very different degrees of value. Some of them are of enormous thickness, exceeding 100 ft., but the cassiterite is not equally distributed in them. It is found in strings and patches and sheets, and many of the veins and large parts of others contain none. The granite veins are very numerous, and a large proportion of them are more or less stanniferous. But the percentage, as elsewhere, is very low, about equalling the average yield of the Cornish mines at present in operation. It is not easy to give figures, but a sanguine estimate might put both at 2 per cent., and probably in order to attain this some of the poorer mineral must be excluded.

The tin works of the Erzgebirge Mountains, between Saxony and Bohemia, are of little importance, but deserve notice because the cassiterite does not occur in distinct lodes, but forms a network of small veins traversing the stanniferous rock. A mine in rock of this kind is called a "stockwork." Cassiterite so diffused is more costly to work than the kinds already mentioned, and were it not that the mines have been operated for many years, and that labour is very cheap and appliances simple, the Saxon and Bohemian tin mines could not remain open. In the stock-works of Altenberg the rock is said to contain 0.33 to 0.50 per cent. of cassiterite. Their yield is constantly decreasing, and from some has already ceased.

But all other deposits of tin fade into insignificance with those of the south-eastern regions of the Eastern hemisphere. The wealth of Malacca has been known for centuries, but only of late years have its enormous stores of tin been brought into the market. The long granite axis of the Malayan Peninsula and its continuation in the Island of Banca is traversed by quartz veins containing tin-stone often so pure that it is of a light brown colour or even translucent. From these veins large quantities of cassiterite have been washed down into the valleys, where it is now gathered. The lodes resemble those of Cornwall, but, if we may judge from appearances, must be vastly richer. No attempts have yet been made to work them. All the tin-stone exported is picked up or washed out in the watercourses, as was formerly done in Cornwall. This is the "stream-tin" of the miner, and its collection is called "streaming." It is in Malacca remarkably free from arsenic, sulphur, and wolfram, but whether or not this same high quality will be maintained in the lodes remains to be seen.

Equal in richness and in value to these are the recently-revealed tin deposits of Queensland and New South Wales. The granitic range of the eastern coast of Australia is the matrix from which the tin-stone has been derived, and all that has yet been done is to mine and wash the stream-tin that ages of erosion have accumulated on the surface and in the watercourses. The workings on Vegetable Creek, in New South Wales, have proved wonderfully productive. Ninety feet of basalt cover the sands and gravels of an ancient buried river bed in which the tin ore was found. Below this and under a bed of pipeclay occur the stanniferous sands and gravels 15 ft. thick above water-level. How far they reach below is not known, as the workings at present cease when the water is reached. Later still the developments in Rose Valley have even surpassed these. From this mine, which closely resembles the other, and lies near it, more ore was taken in 1881 than is produced by any of the Cornish mines, with the exception of some half dozen. These Australian tin lodes reappear in Tasmania on a somewhat smaller scale, and considerable ore is now coming from Hobart, more than 3,000 tons having been shipped in 1881.

The following table includes all the regions that now contribute any appreciable amount to the world's stock of tin, or in which the ore possesses any geological interest:—

	Tons of Metal.
Cornwall (1882)	9,000
Saxony (1880)	170
Italy (1880)	16
Russia (1879)	2
Japan (1875)	7
Penang and Singapore (1882)	15,942
Penang and Singapore (1887)	18,515
Penang and Singapore (1888)	25,594
Banca and Billiton (1882)	8,550
Victoria (1880)	105
New South Wales (1882)	6,500
Queensland (1881)	63,000
Queensland (1882)	16,380
	Tons of Cassiterite.
Tasmania (1881)	3,500

The Lechesne Nickel Steel Process. Iron, 39, 1892, 360.

THE Société du Ferro Nickel, of France, has succeeded in obtaining nickel iron and steel containing a large percentage of nickel, and participating in the remarkable properties of this metal (non-oxidisability, brightness, &c.) and susceptible of being substituted for it in a large number of uses from which it has hitherto been excluded by the high price of pure nickel. In continuing the series of ferro-nickels, the lowering the percentage of nickel below 25 per cent. forms a category of metals the new properties of which constitute a special class of altogether peculiar interest. We have here no longer alloys of a somewhat high price, capable, on account of their richness in nickel, of replacing the pure metal, but metals comparable to iron and steel, and in which the intervention of even a small proportion of nickel modifies the constitution of the metal without (in low percentages) materially increasing its cost, and gives to the iron and steel employed an improvement of quality which is very remarkable.

The process consists in the simultaneous employment of manganese and aluminium with or without the addition of carbon, under the form of charcoal, or metallic or ferro-cyanides. In the case of manganese, either pure manganese is used or oxides mixed with a reducer, or ferro-manganese. In like manner for aluminium, either the pure aluminium is used or a mixture of iron and aluminium. The nickel itself is introduced either in the form of pure metal or in the form of malleable metal, or crude metal more or less rich in nickel, proceeding either from the treatment of nickel ore up to the point of elimination of the iron or from previous fusions of cast iron, wrought iron or steel with nickel. It is preferable to take the pure nickel or mixed with iron at the outset of the operation. The manganese, under whatever form it is employed, mixed or not with the chosen carboniser, is added in one or two increments in the course of fusion. The quantity of aluminium necessary is projected at the close of the operation in the bath of metal or in the casting ladle. The best results are obtained, with proportions of aluminium varying from a ten-thousandth to about one-thousandth, and of manganese varying from one-thousandth to about two hundredths per kilogramme of alloy to be produced according to the quantity of nickel and the quality of the metal to be attained.

From the point of view of the carbonising agents, it has been ascertained that according as it is wished to obtain metal soft or hard, carburetted or not, with the same percentage of nickel, carbon or cyanide must be used in variable proportions. In this way it is possible, by the employment of ferro-cyanide with manganese aluminium, without even the addition of nickel, to transform the iron into a tempered steel naturally susceptible of furnishing turning tools without tempering and by direct forging. We shall give, for instance, the best quantities for obtaining on the hearth a ferro-nickel with 5 per cent. of nickel, starting with a nickelliferous pig. The work is proceeded with as for the manufacture of steel, and after partial or complete decarbonisation, according to the quality of the metal to be obtained, metallic manganese or ferro-cyanide

of manganese is added, and at the moment of tapping the aluminium is added either in the furnace or in the casting ladle. For 500 kilogrammes of alloy the proportions are as follows:—

	Kilos.
Pig with 25 per cent. nickel	100
Soft iron or steel	400
Ferro-manganese with 75 per cent. of manganese ..	3
Aluminium	0.25
Total	503.25

The character of the various alloys is as follows:—

These metals possess a much more perfect homogeneity than that of iron or steel obtained by the usual processes, and consequently they have the qualities of malleability, ductility, tenacity, elasticity, &c., to an altogether superior degree. The coagulation of the ingots is very rapid, and bubbles are avoided. Ferro-nickel, with 25 per cent. of nickel, whatever the quantity of carbon, does not take tempering, but according as the proportion of nickel diminishes, the property of being tempered reappears, and goes on asserting itself until with proportions of 7, 5, and 3 per cent. and below, we obtain alloys capable of being tempered according to laws analogous to those which govern the tempering of ordinary kinds of steel. The proportion of carbon, the distribution and special forms of the carbon in the cement and the metallic core (modification due to the presence of the nickel), the fall of temperature between the heating and the cooling, and the rapidity of the cooling, combine to produce various degrees of hardness, as could be predicted by the complete analysis made according to the very exact methods recently discovered, and by the remarkable investigations into the constitution of steel which have appeared of recent years. The influence of the agents of malleabilisation in the application of these processes is demonstrated by the fact that, when these agents are employed without the intervention of nickel, the products obtained present much superior qualities to those of iron and steel treated by the ordinary processes.

The Specific Heat of Aluminium. J. W. Richards. Journ. Franklin Inst. 1891, **133**, 121–124.

In 1855 Regnault calculated the specific heat of pure aluminium from observations on the crude metal to be 0.2181 between 25° and 97°, and later on as 0.2143 between 14° and 97°. In 1882 Mallet determined the mean specific heat of chemically pure aluminium between 0° and 100° as 0.2253. Recently Naccari obtained the following values:—

15°	50°	100°	200	300
0.2135	0.2164	0.2211	0.2306	0.2401

These values show an increase in the specific heat of 0.0095 per 100° and lead to the formulae—

$$S = 0.2116 + 0.000095 t$$

$$Sm = 0.2116 + 0.0000475 (t_1 + t_2)$$

in which 0.2116 is the true specific heat at 0°. The mean value between 0° and 100° would be 0.2164, agreeing well with Regnault's results, but much lower than Mallet's. The author has determined the specific heat of some aluminium made by the Hall process which consisted of—

	Per Cent.
Aluminium	99.93
Silicon	0.07
Iron	Trace.

Three methods of procedure were used. First, a large weight of aluminium (100–200 grms.) was put into an empty calorimeter, the water equivalent of which had been accurately determined by experiment, and allowed to stand several hours. When the temperature was nearly constant,

a known weight of water at a higher temperature was run in, and the total loss of heat calculated from the observations. This method gave mean specific heats between about 16° and 22°.

Secondly, the aluminium was suspended in steam and dropped into the water in a calorimeter. This gave values from 20° to 100°. Thirdly, two exactly similar calorimeters were used. The aluminium and a platinum ball weighing 52 grms. were placed on a platinum support, and heated together either in an air-bath to 120°, or in a small furnace up to 400°, 500°, and 600°. The platinum ball was dropped into one calorimeter and the lump of aluminium into another. From the heat given out by the platinum its temperature was calculated, and the aluminium was assumed to have been at the same temperature.

The third method gave the most concordant results. The first method was used for such a small range of temperature that the experimental errors were large; the second method was defective in default of suitable apparatus to secure the instant transfer of the metal from the steam into the calorimeter. The third method had the advantage that since the platinum and aluminium were taken out of the furnace together and were dropped almost simultaneously into the calorimeters, it could fairly be assumed that they would cool to about the same extent in the two or three seconds during which they were exposed to the air. The author made two experiments by the first method, five by the second, and 16 by the third. By selecting the most satisfactory experiments and combining the results by the method of least squares the following formulae were arrived at—

$$S = 0.2220 + 0.0001 t$$

$$Sm = 0.2220 + 0.00005 (t_1 + t_2)$$

in which 0.2220 is the true specific heat at 0° C.

From these formulae the following data were calculated:—

Temperature.	True Specific Heat.	Range of Temperature.	Mean Specific Heat.
0°	0.2220	0–100°	0.2270
20°	0.2240		
100	0.2320		
625 (melting point)	0.2845	0–625°	0.2533
Total calorie capacity to the melting point.....			158.3

The author's results thus confirm Mallet's determinations of the true specific heats and Naccari's figures for the rate of its increase with the temperature.—S. B. A. A.

Bearing-Metal Alloys. C. B. Dudley. Journ. Franklin Inst. 1892, **133**, 81–93 and 161–172.

In this paper an account is given of analyses and experiments carried out in the laboratories of the Pennsylvania Railway Company during the last 15 years with the object of determining the most advantageous alloy for use in the construction of bearings for axles, crank-pins, &c. for locomotives and other rolling stock.

Bearings made of alloys have the following advantages over those made of cast iron or of the metal of which the journal is composed:—(1.) The friction between the bearing and journal is in general less. (2.) The alloys melt at a lower temperature, and can be more easily shaped. (3.) The alloys take up the wear and thus save the more valuable journals. A good bearing metal should have the following characteristics:—(1.) It should be strong enough to hold up the load, which in railroad practice is often 350–400 lb. per square inch, without distortion, and it should be able to resist the breaking strain to which the bearings are subjected when they are fitted on worn journals. (2.) It should not heat readily. (3.) It should

be susceptible of treatment in the foundry on the large scale and yield sound castings without requiring great care to prevent oxidation. The addition of 1 to 2 per cent. of zinc or of a small amount of phosphorus in the form of phosphor-tin or other alloy generally leads to this result. (4.) Under given conditions of lubrication, &c. the friction should be comparatively small. (5.) The wear of the bearing with reference to the mileage run should be small. The average bearing loses 1 lb. in weight for every 25,000 miles it has been in use. The common metals from which alloys are made for bearings are copper, tin, lead, zinc, antimony, iron, and aluminium. Sometimes manganese, silicon, bismuth, mercury, cadmium, nickel, cobalt, sulphur, arsenic, and phosphorus, occur either as essential or accidental constituents. The following analyses represent samples of various bearing metals submitted to the Pennsylvania Railway Company during the last 15 years:—

CAMELIA METAL.

Metallic lead and many of the white metal alloys are disadvantageous on account of their inability to resist the breaking strain caused by journals of smaller diameter than the bearings (*i.e.* worn journals) and generally on account of their want of strength.

In copper-zinc alloys the wonderful influence of the addition of a small amount of iron is well seen in the so-called Harrington bronze, the analysis of which is given above. After rolling it had a tensile strength of 75,000 lb. per square inch, and an elongation of 20 per cent. in a two-inch section. The method adopted in testing the wear of the different alloys was to have a certain number of bearings made of a standard alloy, and the same number made of the experimental metal placed on the same axes either on locomotive tenders or on cars, one half of the standard and experimental bearings being on one side of the car and the other half on the other side, so that in all cases a standard and an experimental bearing were on opposite ends of the same axle. The bearings were all carefully weighed before going into service, and after a sufficient lapse of time taken out and reweighed. In this way a sufficiently constant ratio could be obtained between the loss of metal in the experimental alloy and that in the standard, whereas attempts made to determine the wear of an alloy absolutely in terms of the mileage gave unsatisfactory results on account of the variations in the load and state of lubrication of each axle. The Phosphor-Bronze Smelting Company's "S bearing metal," containing approximately 79.7 per cent. of copper, 10 per cent. of tin, 9.50 per cent. of lead, and 0.80 per cent. of phosphorus was used as a standard, and 16 bearings of each kind were, in the first instance, attached to locomotive tenders as a preliminary experiment, and if the metal proved favourable, 50 or 100 bearings of each kind were put in service. In the first test the old copper-tin alloy was compared with the standard with the following result:—

COPPER-TIN v. PHOSPHOR-BRONZE.

	Composition Copper-Tin Alloy.	Composition Phosphor-Bronze.
Copper	87.50	79.70
Tin	12.50	10.00
Lead	None	9.50
Phosphorus	None	0.80

Wear.—First experiment, copper-tin wore 48 per cent. faster than phosphor-bronze; second experiment, copper-tin wore 53 per cent. faster than phosphor-bronze; third experiment, copper-tin wore 47 per cent. faster than phosphor-bronze.

It was also found that a much larger percentage of the copper-tin bearings heated than of the phosphor-bronze. The value of the copper-tin alloy is thus seen to be far inferior to that of the phosphor-bronze. It was then observed that arsenic may practically take the place of phosphorus in a copper-tin alloy.

The following experiments were accordingly made with arsenic-bronze:—

ARSENIC-BRONZE v. PHOSPHOR-BRONZE.

(First Experiment.)

	Composition Arsenic-Bronze.	Composition Phosphor-Bronze.
Copper	80.20	79.70
Tin	10.00	10.00
Lead	None	9.50
Phosphorus	None	0.80
Arsenic	0.80	None

Wear.—Arsenic-bronze wore 42 per cent. faster than phosphor-bronze.

(Second Experiment.)

	Composition Arsenic-Bronze (?).	Composition Phosphor-Bronze.
Copper	79.20	79.70
Tin	10.00	10.00
Lead	7.00	9.50
Phosphorus	None	0.80
Arsenic	0.80	None

Wear.—Arsenic-bronze wore 15 per cent. faster than phosphor-bronze.

(Third Experiment.)

	Composition Arsenic-Bronze.	Composition Phosphor-Bronze.
Copper	79.70	79.70
Tin	10.00	10.00
Lead	9.50	9.50
Phosphorus	None	0.80
Arsenic	0.80	None

Wear.—Arsenic-bronze wore 1 per cent. faster than phosphor-bronze.

It will be observed that the first experiment was practically on a copper-tin alloy containing some arsenic, and that this wore nearly as fast as the ordinary alloy (seven of copper to one of tin), and it may be inferred that the utility of arsenic (and phosphorus) is principally confined to the foundry. In the second experiment the introduction of lead effects a marked diminution of the rate of wear; whilst in the third experiment, in the presence of an equal amount of lead in the two alloys the wear is almost the same, the substitution of arsenic for phosphorus having little influence on the rate of wear or on the heating of the bearings. Accordingly an alloy containing more lead than the standard was prepared and tested with the following results:—

"K"-BRONZE v. PHOSPHOR-BRONZE.

	Composition "K"-Bronze.	Composition Phosphor-bronze.
Copper	77.00	79.70
Tin	10.50	10.00
Lead	12.50	9.50
Phosphorus	None	0.80

Wear.—First experiment, "K"-bronze wore 8 per cent. slower than phosphor-bronze; second experiment, "K"-bronze wore 7.30 per cent. slower than phosphor-bronze, "K"-bronze behaves like phosphor-bronze with respect to heating, &c., the only difference being in the rate of wear. During the progress of the experiments it became apparent that there was a law governing the composition of bearing metal alloys which may be stated as follows:—"The alloy which can endure the greatest amount of distortion without rupture will give the best results in wear." Experiments were accordingly made, first with copper and tin to ascertain what proportions of these metals an alloy capable of enduring a maximum amount of distortion should contain, and then to find how much lead could with advantage be added to this alloy. The proportions selected were 9½ parts

of copper to 1 of tin, but it is now doubtful whether 12 or 15 parts of copper to 1 of tin would not have been preferable. It was then observed that the addition of lead has much the same influence on a copper-tin alloy that a diminution of the tin would have, but that as the amount of tin is diminished and the amount of lead increased the tendency of the metal to yield more readily under pressure increases. As a result of several trials, an alloy "B" was made, which gave the following tests:—

ALLOY "B" c. PHOSPHOR-BRONZE.

—	Composition Alloy "B."	Composition, Phosphor-bronze.
Copper	77·00	79·70
Tin.....	8·00	10·00
Lead.....	15·00	9·50
Phosphorus.....	None	0·80

Physical Properties.

—	Alloy "B."	Phosphor-bronze.
Tensile strength, pounds per square inch.....	21,000	30,000
Elongation per cent.....	11	6

Wear.—Alloy "B" wore 13·50 per cent. slower than phosphor-bronze.

This alloy is now, with a slight modification, the standard bearing metal of the Pennsylvania Railway Company, but it is probable that a still further diminution in the amount of tin and increase of the lead would give even better results; a certain amount of tin is, however, necessary to hold the lead alloyed with the copper. In order to utilise phosphor-bronze scrap and to obtain sound castings, the formula actually in use by the Company is the following:—

	Lb.
Copper.....	195
Phosphor-bronze, new or scrap.....	60
Tin.....	9½
Lead	25½

The product is the Ex. B. metal of which the analysis has been given. By using ordinary care in the foundry, keeping the metal fairly well covered with charcoal during the melting, it is quite possible to get perfectly successful castings in car-bearings with the above formula. The whole of the copper and phosphor-bronze can be charged into the pot before placing in the melting-hole; the tin and lead are added after the pot is removed from the fire.

In conclusion, the author points out that besides a high elongation and tensile strength which are required in an alloy to impede the removal of particles by attrition, there is a third hitherto unconsidered factor which affects the wear, namely, the granular structure of the alloy or the size of the particles which may be torn off. This is probably the most important factor, but there are no data on this point, beyond certain observations, that case-hardened iron wears better than either the wrought iron from which it is made or ordinary hammered steel of approximately the same carbon. Theoretical considerations, however, indicate that a finely granular structure is desirable in a bearing metal.—S. B. A. A.

PATENTS.

An Improved Method of Extracting Copper from Ores or Compounds containing the same. T. D. Nicholls, C. James, Swansea, and the Cape Copper Company, Limited. Eng. Pat. 18,898, November 21, 1890.

The process depends on the reduction of oxides of copper by means of cupric sulphide in a reducing furnace.

One portion of copper matte, preferably containing 76—78 per cent. of copper, is roasted in a current of air until the copper is converted into either cupric oxide or cuprous oxide or a mixture of the two, but preferably into cuprous oxide which is more economical, and this is then mixed with an equivalent quantity of raw copper matte, previously ground so as to pass through a $\frac{3}{4}$ -th screen. The mixture of sulphide and oxides of copper is then heated in a close furnace, when the sulphur unites with the oxygen, sulphurous anhydride passing away, and the copper thus obtained is run into ingots direct.

It is claimed that the process may be worked at about one-half the cost of the usual one, that the volatile impurities contained in the matte are expelled more readily during the evolution of the sulphurous anhydride, than is usually the case, and that by employing a flux, the non-volatile impurities are readily separated. Moreover less copper remains in the slags and in the furnace bottoms than is found in the usual process. Although rich ores are preferred, good results are also obtained when working poor ores containing but 30 per cent. of copper.—J. W. L.

Improvements in the Manufacture of Refractory Materials or Articles. J. B. Alzugaray, London. Eng. Pat. 21,212, December 30, 1890.

It is recommended to make the inner wall or lining of crucibles of a layer of finely ground coke, plumbago, graphite or other form of carbon, whilst for the outer coat, mixtures of different infusible materials are recommended.

The different mixtures named are made up of several of the following materials: finely pulverised emery, asbestos, chalk, limestone, graphite, retort-coke, bauxite, quartz, magnetic oxide of iron, kaolin, fire-clay, magnesite. The materials are all finely ground and mixed with about 10 per cent. of their weight of tar or oil, or other carbonaceous material. If desired, on account of economy, to insert between the outer coat and the inner lining a third layer of some cheaper material, this may be done, for which purpose any infusible material that is without action on the other materials may be used.—J. W. L.

Improvements in the Process of Coating or Cleaning Metals. R. Heathfield, Darlaston. Eng. Pat. 500, January 10, 1891.

In order to avoid the use of acids in cleaning the surface of metals before galvanising, the objects to be cleaned are immersed in a solution of ferrous sulphate or chloride, and connected with the positive pole of a dynamo, whilst another set of objects are connected with the negative pole. Metal is dissolved off the surfaces of the objects acting as the anode, and a corresponding quantity deposited on those of the objects which constitute the cathode, a great saving of expense being thus effected.—J. W. L.

Improvements in Treating Waste Liquor from Galvanising Works and other similar Liquors to obtain Ferric Chloride. J. W. Wilson, Manchester, and C. H. G. Harvey, London. Eng. Pat. 6509, April 16, 1891.

See under VII., page 433.

A Process of Using Galvanisers' Wastes. R. J. Brice, London. Eng. Pat. 15,288, September 9, 1891.

The two products which constitute galvanisers' waste, are "sal-ammoniac skimmings" and "zinc-ashes." In order that the skimmings may be economically worked, they should be preserved in casks until required.

The sal-ammoniac skimmings are fused, preferably in an iron pot, the metallic zinc melts and is drawn off at the

bottom, the "waste" is then transferred to boiling water, when it becomes reduced to a fine state of subdivision. Milk of lime is now added to the water containing the waste, in quantity equal to about 20 parts of quicklime to 100 parts of skimmings operated upon. Calcium chloride and zinc oxychloride are thus formed. The solution containing the former is separated, and any ammonia it may contain is separated by the addition of a little more milk of lime and then distilling.

The precipitated zinc oxychloride may be pressed from the liquid, and used as a pigment by itself, or it may be mixed with zinc ashes in quantity equal to the weight of skimmings operated upon, when the pasty mass is dried and calcined, when it becomes much lighter coloured, and forms paint of more than ordinary body and durability. Before mixing the zinc ashes with the precipitated zinc oxychloride, they are screened from the rough particles of metallic zinc.

—J. W. L.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

Quantitative Analysis by Electrolysis. F. Rüdorff.
Zeits. f. angew. Chem. 1892, 3—7.

See under XXIII., page 459.

Hoeftner's Electrolytic Copper Process. Eng. and Mining J. April 30, 1892, 471.

This process differs very materially from that of Siemens, in that the copper is precipitated from a cuprous chloride solution, wherein is a great advantage, for the same current will deposit copper from a cuprous chloride solution just twice as fast as from a sulphate solution.

While copper sulphate solution is used in the Siemens and Halske process for the electrolytic separation of copper, Dr. Hoeftner, of Giessen, uses in his process a cuprous chloride solution which deposits 2.36 grms. of copper per ampère hour. The liquid, which is a solution of cuprous chloride in strong brine, or in a concentrated solution of chloride of lime, and which contains 120 grms. of copper per litre, flows through an electrolytic bath with vertical electrodes, in which the anodes and cathodes are separated by diaphragms, but in such a way that there is nevertheless a constant circulation of the solution along both electrodes. At the cathodes metallic copper is deposited from the solution.

If the separate cathodes of such a bath have each a surface of one square metre and the current be 50 amperes per square metre, then there will be deposited on that surface, according to theory, 2.76 kilos. of copper per 24 hours, and Hoeftner asserts that with careful work he can obtain 90 per cent. of the quantity. The loss of 10 per cent. is due to diffusion of the cupric chloride from the anodes through the diaphragm to the cathodes.

The solution flows continuously from the cathode cells after having passed a large number of them and after having deposited its copper. That portion of the cuprous chloride solution which has been flowing during the same time continuously through the anode cells retains its copper entirely, but, owing to atomic changes, free chlorine is generated at the carbon anodes naturally proportionate in quantity to the amount of copper deposited at the cathodes. The nascent chlorine, of course, attacks the cuprous chloride, changing it to cupric chloride, and thereby developing positive electromotive force; that is, electromotive force tending to precipitate more copper at the cathodes, so

that the electrolysis will take place even if there be more than 0.6 to 0.8 volt for each bath, while double that potential would be not necessary if there were no such chlorine depolarisation.

The cupric chloride at the end is mixed with the cathode solution now freed of its copper, and this mixed solution then should contain, according to the theory of the process, only one-half as much copper as before electrolysis, or about 60 grms. of copper per litre.

The copper is now, however, no longer in the form of cuprous chloride, but is present as cupric chloride. It is well known that this latter chloride, heated as a dry powder, will lose half its chlorine, which goes off as free chlorine gas. In solution this salt is well adapted, notably when heated, to dissolve sulphides, especially that of copper from its ores, precipitating free sulphur. On the sulphides of silver it acts in the same way, and of this dissolving power Hoeftner makes practical use.

The copper ores, which may also contain silver, are ground very fine in a Gruson mill, either crude or after having been roasted. They are then raised by an elevator to a platform above the leaching barrels, to which they are afterwards transferred as needed.

The leaching barrels are of wood, of a capacity of 10,000 litres each, and rotate on fixed iron wheels, the rotary motion being obtained by sprocket wheel and chain. There must be three or four such barrels. Each of them is filled with 8,000 litres of the heated solution and a corresponding amount of the ore to be treated, and is then set in motion. The time necessary for the leaching varies of course with the character of the ore. It takes from two to six hours to reduce the cupric chloride solution to the cuprous chloride. In practice the so-called "Methodical Leaching" is resorted to, that is, every portion of ore is leached out twice, first by a solution containing a smaller amount of the cupric chloride, and then by another very rich in that salt, which latter solution takes out the remainder of the copper completely.

When the solution has been sufficiently regenerated, the rotation of the barrel is stopped, the particles of ore fall to the bottom, and the clear solution is drawn off. The solution is then cleaned both mechanically and chemically in special apparatus.

Besides holding copper, the solution contains silver, and certain small quantities of such impurities as lead, iron, arsenic, &c. These are first removed, so as to obtain in the electrolysis afterwards a perfectly pure copper. The silver can be precipitated either chemically or electrolytically. An analysis of the copper deposited by the process of Dr. Hoeftner from very impure ores showed only very small quantities of impurities, which were not sufficient to influence in any way the quality of the product.

The advantages of this product are, according to the inventor: 1. The process yields per unit of current just twice as much copper as a sulphate process. 2. The silver in the ore, which often is of great value, will also be obtained. 3. The conductivities of the solutions are very good and their dissolving power is great.

After having been cleaned the solution goes to the baths for electrolysis, passes through them, and comes out again as a cupric chloride solution, which is again used as a solvent. It is therefore a continuous process, in which the solution circulates constantly, dissolving and precipitating copper in its various stages.

The ore is forced from the barrel in the form of a thick mush, which is washed in a filter-press. It is due to this latter circumstance, i.e., the use of the filter-press, and to the compactness of the plant, that the process requires very little room.

The electrolytic plant for a daily production of 2,000 kilos. of copper needs only 800 square metres, while the entire plant, including machinery and all, would require not more than twice that area.

Since the foregoing article was written, many improvements have been made, one of the most important of which is the abandoning of the carbon anodes. These being so expensive, Hoeftner tried to replace them by another substance, and was finally successful last summer in finding a very cheap anode, and which, like the carbon anodes, does

not dissolve. The analysis of the copper obtained from very impure ores, which is referred to near the end of the article, was made in Fresenius' laboratory in Wiesbaden. The results were as follows:—Sulphur, 0.0004 per cent.; iron, trace; arsenic, trace; antimony, trace; lead, trace; nickel and cobalt, 0.0012 per cent.; molybdenum, 0.0023 per cent. In other words, this copper was as pure as the best copper.

PATENTS.

Improvements in Cells for the Electrical or Storage Batteries, and the Manufacture of Lead for the same. T. W. Bush, Broseley, and M. Doubleday, Nottingham. Eng. Pat. 2471, February 11, 1891.

THE process consists in pouring molten lead into water, or acid, or alkali diluted with water. The material so obtained, named "hydrolised lead," may be placed in vessels separated by porous partitions, each compartment forming a plate. Grids may be placed in the liquid, and then the material is reduced by pressure into uniform thickness; or the grids may be replaced by cocoa-nut matting. This material is also used for separators after being impregnated with plaster of Paris. The plates are held together by wood or vulcanite screw-bolts, thus avoiding the use of binding frames.—G. H. R.

Improvements in Voltaic Cells. H. H. Lake, London. From E. Weston, New Jersey, U.S.A. Eng. Pat. 22,482, December 23, 1891.

THE object of this invention is to provide a standard cell whose electromotive force shall be practically independent of temperature. This may be accomplished in one of three ways: firstly, by using as an electrolyte a saturated solution of cadmium salt with electrodes of other material; secondly, by using an electrode containing cadmium opposed to mercury in a solution of some salt other than cadmium; thirdly, and this is best for a permanent standard cell, cadmium amalgam in a saturated solution of cadmium sulphate opposed to mercury in mercurous sulphate.

—G. H. R.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

The Solid Fatty Acids of Palm Oil. H. Nördlinger. Zeits. f. angew. Chem. 1892, 110—111.

STATEMENTS of text-books point to the possibility of easily obtaining pure palmitic acid by crystallising the palm oil acids from alcohol. The author did not succeed by proceeding in this way, and undertook, therefore, the examination of a specimen of pure Lagos oil, melting at 38° C., and containing 50.8 per cent. free fatty acids (calculated for oleic acid). The oil was saponified and the fatty acids separated by means of sulphuric acid and washed repeatedly with water. The fatty acids were divided into two parts. (Although the author speaks only of the solid fatty acids of the palm oil, he does not state whether and how he separated the solid fatty acids from the liquid acids of the palm oil.)

The author claims the existence of a heptadecylic acid in palm oil, which may be identical with Gerard's daturic acid (this Journal, 1889, 1137), melting point 55° C.

The solid fatty acids of palm oil consist, according to the author, of 98 per cent. palmitic acid, 1 per cent. stearic acid, and 1 per cent. heptadecylic acid.—J. L.

PATENTS.

Manufacture of Fatty Matter from Wool-Fat. F. C. Glaser, Berlin. From O. Braun and O. Liebreich, Berlin, Germany. Eng. Pat. 4992, October 20, 1882. (Second Edition.)

A DESCRIPTION of this process has already appeared in this Journal, 1883, 182; (Braun and Liebreich, U.S. Pat. 271,192). The inventors obtain from the wash-waters of wool-seouring works or from impure commercial wool-fat by means of a hydro-extractor a purified wool-fat, which has the property of combining with water, thus forming a white inodorous, neutral unguent. This purified wool-fat has been termed by the inventors "Lanolin."—J. L.

Improvements in Lubricants for Heavy Machinery. C. H. Ridsdale, Guisborough, and A. Jones, Middlesbrough. Eng. Pat. 3782, March 3, 1891.

IN order to avoid the waste attending the usual method of applying the lubricant to heavy machinery, such as necks of rollers in iron or steel rolling mills, the patentees prepare the lubricant in solid form as blocks, bars, slabs, &c. They use ordinary soap, or an alkali or alkaline earth, or a mixture of both, and add to this mixture saponifiable oils or fats in quantities suitable to produce the hardness required for the special purposes, if the soaps are mixed with mineral oils or mineral lubricants, such as black lead, sulphur, mica, &c. Two recipes will illustrate the composition of these lubricants:—

	Per Cent.
Hard Lubricant:—	
Lime or magnesia.....	3
Ordinary soap.....	6
Rendered suet.....	75
Fine black lead.....	16
Soft Lubricant:—	
Lime or magnesia.....	2
Rendered suet.....	45
Sulphur (fine).....	14
Black lead.....	19
Heavy petroleum oil.....	30

—J. L.

Improvements in the Manufacture of Soap, and in the Utilisation of the Residue of the Substances used therein. R. Stone, London. Eng. Pat. 4454, March 12, 1891.

THE novelty of this invention consists in the use of a combination of fruits or of vegetables. The inventor soaks these materials in 10 per cent. of glycerin or almond oil or palm oil, and mixes the juice expressed from these substances "of a nutritious and skin-healing nature" with soap. For such a soap the property is claimed of being "especially soothing and healing to the skin."

The residues obtained from the soaked material are baked or dried and ground up. This material is to be used as a substitute for coffee, being alleged to be "far more nutritious for the human system than ordinary coffee."—J. L.

Improvements in the Thickening of Oil. W. N. Hartky, Dublin, and W. E. Blenkinsop, Wandsworth Common. Eng. Pat. 7251, April 27, 1891.

LINSEED oil may be thickened and thereby converted into a suitable material for manufacturing oil-skin, oil-silk, oil-cloth, floor-cloth, linoleum, linerusta, &c., by adding a solution of one part of manganese soap or manganese linoleate—as prepared in the manner described in Eng. Pat. 11,629, 1891 (this Journal, 1891, 263)—in two parts of turpentine to the oil to be thickened. Two or five volumes of this soap solution are used for 100 volumes of the oil to be treated. Insoluble matters are allowed to settle out and are removed. The mixture is raised to a temperature of

212° F. (in an apparatus described in Eng. Pat. 11,629) and a current of air or oxygen passed through the oil until it acquires any desired degree of thickness. Thus, *e.g.*, from a linseed oil, sp. gr. 0.937, a clear transparent oil of a pale amber colour, sp. gr. 0.997 (at 70° F.), has been obtained.

Cotton-seed oil may be thickened in the same manner; the patentees use for this oil one volume of linoleate solution to 400 volumes of cotton oil.—J. L.

A New or Improved Method of Treating Oils used for Lubricating and Tempering Purposes, to render the same Incombustible or Fireproof. R. R. Graf, Baltimore, U.S.A., Eng. Pat. 29,512, November 25, 1891.

THE object of the "inventor" is to render lubricating oils incombustible and fireproof, and he proposes to do this by triturating 32 parts of sodium tungstate, 32 parts of sulphate of ammonia, 18 parts of phosphate of ammonia, 12 parts of sal-ammoniac, and 24 parts of sodium monocarbonate in a mortar with sufficient linseed oil to obtain a paste of even consistency, and finally mixing this paste with 520 parts of any suitable heavy oil. It is claimed that this mixture has all the good properties of a lubricant, "the oil being in all respects just as good as before treatment," and can be applied not only to fast-running machinery, as dynamos and electric motors, but also be used with great advantage in tempering steel tools.—J. L.

An Improved Manufacture of Superfatted Soap. C. L. Field, London. Eng. Pat. 21,438, December 8, 1891.

THIS improvement in the manufacture of superfatted soaps consists in adding to soap, made by the cold process, milk, cream, or butter in such quantities that any alkali in excess is saturated and an excess of cream is left.—J. L.

Improvements in Candles or Tapers for Fumigating or Perfuming or Evaporating Purposes. J. Ryder, Manchester. From E. A. Weidemann, Liebenburg, Germany. Eng. Pat. 22,742, December 30, 1891.

CANDLES or tapers for fumigating purposes are manufactured in such a way that the substances, the vapours of which are to perfume or disinfect the air of a room, are closely enveloped by the ordinary material of the candles or tapers. This is effected by either incorporating the perfuming substances with the material of the candles or filling them into tubes which are embedded in the candle material.—J. L.

Improvements in Cauldrons for Melting Pitch and Fatty Substances. B. D. Healey, Bamber Bridge. Eng. Pat. 324, January 7, 1892.

THE invention relates to a mechanical improvement of an apparatus previously patented by the same inventor (Eng. Pat. 11,443 of 1891), and consists essentially in an improved method for drawing off gas and air from the cauldrons and for making the bogie or swivel box for the front wheels of the cauldrons. For details the drawings accompanying the specification must be consulted.—J. L.

Improvements in Process and Apparatus for Extracting Glue or Gelatin and Grease out of Hide and Skin Waste and of Bones at comparatively Low Temperature. L. Bertram, Berlin, Germany. Eng. Pat. 951, January 18, 1892.

See under XIV.—page 447.

Improvements in Cages for Oil Presses. A. Estrayer, Marseilles, France. Eng. Pat. 2264, February 5, 1892.

THE improvement consists in building up the interior of the cage of eight sections which are made to open and close by means of a vertically moving outer cylinder. For details the sheet of drawing should be consulted.—J. L.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

PATENTS.

An Improved Waterproofing and Rust-Preventing Composition, applicable also in the Manufacture of Ink. F. L. Beech, Middleton Junction, and A. Horrobin, Hollinwood. Eng. Pat. 1616, January 29, 1891.

THIS invention has for its object the providing of a solution by which paper, leather, &c., can be waterproofed. The liquid is also applicable as a coating for walls, as a rust-preventer for machinery, and, mixed with colour, as an indestructible ink. The ingredients used are turpentine, asphaltum, resin, alum, and bees'-wax.—E. G. C.

Improvements in the Manufacture of Copying Ink. E. Corn, Turin. Eng. Pat. 3247, February 23, 1891.

THE following are the ingredients of this ink:—Ordinary ink, 690 parts; candied or twice refined sugar, 225 parts; and pure glycerin, 85 parts.—E. G. C.

Improvements in or relating to Sulphuretted Solutions and Compounds used for the Production of Films or Coatings. J. S. Fairfax, London. From F. Crane, New York, U.S.A. Eng. Pat. 3345, February 24, 1891.

THE object of this invention is to produce a substance or compound which is not injuriously affected by exposure to the air, and is waterproof. Such a substance has many applications, as a coating for paper, leather, textile fabrics, or as a substitute for india-rubber in some of its applications. For the purpose, a combination of soluble pyroxylin with sulphuretted oil is employed by the inventor; and good results are stated to have been yielded by the following formula:—Butyl acetate, 7 gals.; petroleum naphtha, 3 gals.; pyroxylin, 15 lb.; sulphuretted oil, 30–40 lb.; and any desired pigment, 1–2 lb.—E. G. C.

Improvements in the Method of and Apparatus for Manufacturing Inlaid Linoleums or Floor Cloths. W. G. Thomson, Halifax, and J. S. Powell, London. Eng. Pat. 4240, March 10, 1891.

See under VI., page 431.

Improvements in the Manufacture of Coloured Rubber Goods or Rubber-Coated Goods, and a Material or Preparation to be used in the said Manufacture. C. Dreyfus, Clayton. Eng. Pat. 17,566, October 14, 1891.

THE inventor states that hitherto colours produced on rubber-coated fabrics have been mechanically mixed with the rubber solution, or with the "swelled" rubber, prepared in the usual way with so-called solvent naphtha. The

novelty claimed is the use of a coloured solvent for the rubber, the lakes produced by treating an aqueous solution of resin soap with metallic salts, or salts of an alkaline earth, and a basic coal-tar dye, being dissolved in the "dissolving naphtha" of commerce, or in benzene. The rubber is then added.—E. G. C.

Improvements in Mucilages, Sizes, and Adhesive Compounds. C. M. Higgins, Brooklyn, U. S. A. Eng. Pat. 22,679, December 29, 1891.

DEXTRIN, 7—9 lb., is dissolved in water, 1 gal., at a temperature of 60°—100° F., and after the solution is cool, half a pint to one pint of 15 vol. hydrogen peroxide solution is added. The patentee claims the production of an "adhesive compound" and the application of hydrogen peroxide as above. The effect of the last-mentioned ingredient is to increase the solubility of the dextrin and to prevent the separation of "dense grayish sediment" which usually takes place when it is not used. "Yellow dextrans act better than white dextrans, but either may be used."

—A. R. L.

Improvements in Mucilages, Sizes, and Adhesive Compounds. C. M. Higgins, Brooklyn, U.S.A. Eng. Pat. 22,682, December 29, 1891.

THE patentee claims the production of an adhesive compound by heating a solution of dextrin and borax in water, and the thickening of the same with an alkali. His invention differs from that specified in U.S. Pat. 244,200 of 1881, in that a larger quantity of borax relatively to that of dextrin, viz., $\frac{1}{16}$ — $\frac{1}{4}$ the weight of the latter, is used, and the mixture is heated or boiled to effect chemical combination. For an ordinary "strong mucilage," the following proportions are used:—Dextrin (preferably white dextrin) is dissolved in an equal weight of water (at 60°—150° F.), together with $\frac{1}{2}$ its weight of borax; to the cool solution $\frac{1}{16}$ — $\frac{1}{4}$ its volume of ammonia (20° B.) or caustic soda lye (40° B.) is stirred in, when the solution suddenly thickens, accompanied by a rise in temperature of about 6° F., and the adhesive qualities of the mixture become considerably enhanced; the order in which the ingredients are mixed cannot be varied. When a saturated solution of alum is added to the solution of borax and dextrin, and subsequently an alkali, the mucilage becomes extremely viscous and adhesive. The mucilage may be dried into a solid granular gum, which is dissolved in water as required. In certain cases dextrin and borax may be mixed together in powder, and when this mixture is dissolved in hot water it yields a very adhesive mucilage on addition of ammonia or other alkali. "The improved compound may be used for sizing paper or textile fabrics, also for size in kalsomine or other washes or paints."—A. R. L.

Improvements in Mucilages, Sizes, and Adhesive Compounds. C. M. Higgins, Brooklyn, U.S.A. Eng. Pat. 22,685, December 29, 1891.

THE patentee describes the production of an "adhesive compound" formed by dissolving dextrin and borax in water, as specified in the last abstract, and stirring into the cool solution $\frac{1}{16}$ — $\frac{1}{8}$ of its volume of 15 vols. hydrogen peroxide which clarifies it. After a few days or weeks, the clear supernatant liquid is drawn off and bottled, or in some cases $\frac{1}{16}$ — $\frac{1}{4}$ its volume of ammonia (20° B.) or of soda lye (40° B.)—a mixture of alum and sodium carbonate may also be used—is added to thicken it. He claims that the mucilage thus obtained is equal or superior to that produced from natural gums, at the same time being much less costly. The "improved compound" may be used for the same purposes as that described in the preceding abstract, and "for any similar uses where a size,

fixative, stiffening, or adhesive substance is required. Sometimes a second addition of hydrogen peroxide is made, which has the effect of rendering the mucilage still clearer and purer.—A. R. L.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

Analysis of "Eggio." C. S. Boyer. Journ. Franklin Inst. 1891, 133, 205—206.

"Eggio" is a preparation of the yolk of eggs, and is used for the dressing of fine leathers. Only the ingredients valuable for this purpose, namely, water, ash, and fatty acids, were determined. The results were as follows:—

	I.	II.	III.	IV.	V.
Water	55.64	$\left\{ \begin{array}{l} 56.81 \\ 56.06 \end{array} \right.$	$\left\{ \begin{array}{l} 56.91 \\ 56.45 \\ 56.79 \end{array} \right.$	54.20	$\left\{ \begin{array}{l} 53.75 \\ 53.62 \end{array} \right.$
Ash	$\left\{ \begin{array}{l} 11.73 \\ 11.80 \end{array} \right.$	19.25	$\left\{ \begin{array}{l} 9.46 \\ 9.47 \end{array} \right.$	13.67	16.35
Fatty acids ..	14.66	16.00	15.23

The water was determined by mixing with ignited sand and drying for 2—4 hours at 110° C.; the ash left on igniting the residue was light grey to white in colour and free from lime.

From a comparison of the analyses with values obtained from pure egg yolk it appears that commercial "eggio" contains from 2 to 5 per cent. more water, and from $3\frac{1}{2}$ to 6 per cent. less fatty acids. The high ash is due to sodium salts added to prevent putrefaction.—S. B. A. A.

PATENT.

Improvements in Process and Apparatus for Extracting Glue or Gelatin and Grease out of Hide and Skin Waste and of Bones at comparatively Low Temperature. L. Bertram, Berlin, Germany. Eng. Pat. 951, January 18, 1892.

GLUE or gelatin of the best quality are only obtained when the extraction is carried out at a low temperature. The inventor proposes for this purpose an apparatus in which the raw material is extracted at a temperature of 75° to 85° C. The apparatus consists essentially of a water-bath which can be heated either by a steam coil placed inside the water-jacket or by a separate steam compartment fastened to the bottom of the vessel. Inside the water-bath the inventor places a vessel made of sheet iron and tinned inside and furnished with a false bottom made of the same material on which the raw material to be extracted is placed and covered with water. By two or three extractions the most valuable parts are obtained; the last quantities are recovered by boiling the material with direct steam, for which purpose the innermost vessel is provided with a lead steam coil. To increase the heating surface of the water-bath hot water tubes communicating with the water-jacket protrude into the inner vessel, in which the extraction is carried out.

There are six claims and one sheet of drawings.—J. L.

PATENTS.

Improvements in the Refining or Extraction of Sugar from Raw Sugar Solution, Juice, or Molasses. A. Schneller and W. J. Wisse, The Hague, Holland. Eng. Pat. 5236, March 24, 1891.

A SCRUBBER in the form of a tower is packed with broken brick, earthenware, china, or glass, and the solution containing the raw sugar juice or molasses is thrown in a spray upon the top portion of it. As it trickles over this surface in a downward direction, ozonised air, produced according to the process specified (Eng. Pat. 5222 of 1891; this Journal, 1892, 354), is caused to enter at the lower part of the scrubber, and coming into close contact with the solution, oxidises the impurities contained therein. The solution afterwards collects in a reservoir at the bottom of the scrubber, and is again (as often as necessary) treated in a similar manner in the same, or preferably another scrubber. With more than one scrubber the process may be carried on without interruption. The spent ozonised air may be used for bleaching or other suitable purpose, but if it be desired to destroy the ozone in it, it is led into a furnace.

—A. R. L.

Improvements in and Apparatus for Converting Amylaceous Substances into Soluble Products. W. P. Thompson, Liverpool. From A. H. J. Bergé, Brussels, Belgium. Eng. Pat. 7272, April 27, 1891.

THE patentee claims an improved process for the conversion of amylaceous substances such as "starch, flour, or farina, ground, bruised, or even whole grain" into dextrin-like products in a dry state by means of gaseous sulphurous anhydride; the products being soluble in either warm or

cold water. This may be effected in a closed vessel containing the substances, together with sulphurous anhydride, heated by an oil-bath, but a more uniform action is insured by the use of an apparatus described in the specification. It consists of a cylindrical vessel supported at its extremities by two hollow trunnions in pedestals, and capable of revolving on its longitudinal axis; a steam coil, fed by a tube branching from one of the trunnions, the steam escaping by two pipes provided with valves having an exit at the other trunnion, is placed within the vessel; the trunnions are fitted with stuffing boxes to avoid the escape of steam. A man-hole is attached, capable of being easily opened and hermetically sealed. The vessel is half filled with the amylaceous substance, and gaseous sulphurous anhydride passed in until the air is displaced, when the exit tube is closed, and when the vessel is full of sulphurous anhydride, the temperature is raised from 120° to 190° C., according to the nature of the desired product. When the conversion is complete, the sulphurous anhydride is allowed to escape.—A. R. L.

Improvements relating to the Manufacture of Cube-, Loaf-, and Similar Sugar. W. P. Thompson, Liverpool. From J. Hirsch, Grünau, Germany. Eng. Pat. 21,477, December 8, 1891.

THE patentee claims that his invention provides a method of directly preparing the sugar obtained by the Steffen washing process, or by any other process of refining for table cubes, loaves, &c., without dissolving, clarifying, or filtering such sugar.

A warm mash is prepared in a receptacle above a vacuum apparatus, and in the mash white sugar is mixed with a clarifying liquid or water to a thick paste, and carefully warmed. The vacuum pan is then charged with the mixture, closed, and the air pump applied; the liquid sugar is then brought to the required temperature and finally drawn off. "Blued clear, or blued pure water" is then added to it, and it is boiled down until of the necessary firmness, the masseculite thus obtained being put into moulds to be made into cubes, loaves, &c.—A. R. L.

Improvements in Mucilages, Sizes, and Adhesive Compounds. C. M. Higgins, Brooklyn, U.S.A. Eng. Pats. 22,679, 22,682, and 22,685, December 29, 1891.

See under XIII., page 447.

Improvements in Refining Sugar. E. Langen, Cologne, Germany. Eng. Pat. 420, January 9, 1892.

THE patentee claims that his invention provides a method whereby the total sugar obtainable by crystallisation from the after-products of the refining process is led back into the circuit of this process in the form of an almost chemically pure sugar solution.

A filtered solution of raw sugar is boiled down to a granular filling mass in the usual manner to obtain No. 1 product of the refining process. The first so-called green syrup is concentrated to a granular consistency, and the resulting mass is agitated with sugar crystals to induce crystallisation, according to the Wulff or Boek process; it being then divided according to Steffen's process of "fractionated washing" into a whitish crystalline magma, consisting of No. 11. product, and low-grade syrup. After pumping off the low grade syrup (see below) from the magma, water is distributed uniformly over its surface in thin streams, whereby all the sugar passes into solution. If the first portion of the solution issuing from the washing vessel be coloured, it is used as boiling liquor for No. 1. product; whilst that subsequently pumped out is employed for the preparation of the clear liquor. The low-grade syrup from No. 11. is concentrated and made to crystallise as described above, the mass produced being subjected to

centrifugal action, and the yellowish granular sugar (No. III. product) used for inducing the crystallisation of No. II. product. The syrup obtained from No. III. product is, as a rule, sufficiently low for treating as molasses, but when this is not so, it may be again subjected to the crystallisation process and No. IV. product obtained, the latter being used to induce the crystallisation of either No. II. or No. III. products.—A. R. L.

XVII.—BREWING, WINES, SPIRITS, Etc.

The Decomposition of Manitol and Dextrose by the Bacillus Ethacetius. P. F. Frankland and J. S. Lumsden. Proc. Chem. Soc. 1892 [110], 70—72.

The products of the fermentation of both these compounds consist of ethyl alcohol, acetic acid, carbonic anhydride, hydrogen, and traces of succinic acid. When the fermentations are conducted in a closed space there is invariably also a considerable quantity of formic acid produced, whilst in fermentations in an open space (flasks plugged with cotton wool) formic acid, except in traces, is a most exceptional product. The same phenomenon has been already pointed out by one of the authors in the case of a fermentation with another organism (*B. ethacetosuccinicus*), and it is doubtless due to formic acid being one of the primary products of the fermentation, and then breaking up, more or less completely, into equal volumes of carbonic anhydride and hydrogen; this decomposition is, however, retarded when the products—carbonic anhydride and hydrogen—are prevented from escaping, as is the case in fermentations conducted in a closed space. Indeed, the proportion in which the carbonic anhydride and hydrogen were found coincides almost exactly with that in which they are present in formic acid. The proportions in which the several products are obtained from manitol is approximately represented by the equation—

whilst in the case of the dextrose the products occur in the proportions—

Thus, there is more acetic acid in proportion to alcohol and formic acid produced in the case of dextrose than in that of manitol. The carbon dioxide given among the products really represents that liberated from the calcium carbonate present in excess by a fixed acid insoluble in ether, the nature of which could not be determined.

The fermentations conducted in a closed space are always found to be markedly less complete than those which take place in an open one.

There is a close qualitative and quantitative resemblance between these fermentations by the *B. ethacetius* and those previously described by one of the authors as taking place through the agency of the *Pneumococcus* (Friedländer), which renders it probable that this ethacetic decomposition is a very general and typical form of fermentative change.

In reply to a question by Dr. Kipping, he added that it was very remarkable that, notwithstanding both alcohol and acetic acid were formed, no trace of ethylic acetate could be detected among the products.

PATENT.

Improvements in the Process of and Apparatus for Brewing Beer. D. Quertain, Lobbes, Belgium, and H. Becker, Charleroi, Belgium. Eng. Pat. 654, January 13, 1891. (By International Convention), June 14, 1890.

THE "invention consists of a new process for the brewing of beers by one continuous work and by natural decantation by means of new or improved apparatus, and the object of the invention is to obtain a more rapid manufacture to prevent evaporation, to prevent the formation of a head, and to obtain a beer as strong as those now manufactured, at the same time employing a less quantity of malt." In details of this invention the original specification must be consulted.—A. L. S.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A).—CHEMISTRY OF FOODS.

On the Chemistry of the Preserve Industry. W. Renss. Chem. Zeit. 1891, 15, 1522—1523, and 1583.

THE author noticed the presence of lead in some preserves put up in tinned-iron canisters, the latter were constructed by bending the sheet-metal together, thereby avoiding contamination with lead by means of solder and hermetically sealed by india-rubber bands. He subsequently traced the lead to these bands, which contained this metal in the form of minium. On examining red india-rubber bands of French, German, and English manufacture, he found them to contain as much as 60 per cent. of minium.

PATENTS.

Improvements in Means for Storing and Preserving Food for Domestic Uses. L. Smith, Chicago, U.S.A. Eng. Pat. 2444A, February 10, 1891.

IT is a well established fact that canned goods undergo a change, and that their delicate flavour is either entirely destroyed or sufficiently altered to render them more or less unpalatable. The cold-storage system also has its disadvantages, apart from the great expense, as food thus preserved must not be kept for any length of time after removal from the cold storage, as it is known to perish very rapidly.

The invention consists in storing the goods in an air tight receptacle from which the air can be exhausted, while carbonic acid is allowed to take its place. This gas, as is well known, has little or no effect upon articles of food, and does not alter their flavour or impart to them an unpalatable taste to any great extent. For further particulars the original specification must be consulted.—L. de K.

Improvements in the Manufacture of Soap and in the Utilisation of the Residue of the Substances Used therein. R. Stone, London. Eng. Pat. 4454, March 12, 1891.

See under XII., page 446.

A New Chemical Food. A. D. McKay, Liverpool. Eng. Pat. 279, January 6, 1892.

To be utilised as food by young children or aged persons who are unable otherwise to retain or assimilate it, milk is subjected to special treatment. The invention consists in adding to the milk, which is preferably first condensed, a large proportion of sugar and pure dextrin, a small quantity of albumen, and a very small amount of both sodium and calcium hypophosphites.—L. de K.

(B.)—SANITARY CHEMISTRY.

Drinking Water and Disease. W. P. Mason. Jour. Franklin Inst. 1891, 132, 356—365.

The author comments on the prevalent ignorance of the pathogenic significance of the presence of fresh-water algae in our city water supplies; he is also inclined to regard water polluted by sewage from healthy persons as less harmful than sewage from pathological sources. Referring to the self-purification of polluted water in running streams, he is of opinion that a very considerable self-purification does take place in running streams, but that what holds good for dilute sewage does not necessarily apply to waters as they approach the limit of potability; in fact, he believes that the rate of self-purification varies directly as the amount of sewage contamination, and therefore, given a stream with a certain amount of pollution, the percentage of this disappearing per mile should continually decrease as the stream flows on. His views find support in the analytical investigations of Dr. Long on the water of the Illinois and Michigan canal. This canal receives its supply of water, or rather dilute sewage, at Bridgeport; it then flows along the level to Lockport, 29 miles below, requiring about a day for its passage. It receives no dilution on the way, but is frequently agitated by passing boats, and it is distinctly shown, by a great number of analyses of samples taken on various dates, but at both Bridgeport and Lockport on the same days, that when the free ammonia, the albuminoid ammonia, and oxygen consumed were very high, the amount of reduction was considerable, and that when they were low the amount of reduction was insignificant. Taking two sets of analyses for example, the numbers obtained are:—

	Free Ammonia.	Albuminoid Ammonia.	Oxygen consumed.
June 6, at Bridgeport.	2.6	0.64	12.0
Aug. 25, at Bridgeport	29.2	1.90	35.2
June 6, at Lockport.	2.8	0.56	11.35
Aug. 25, at Lockport.	13.0	0.88	12.10

This result is better shown in the paper by diagrams giving the numbers mapped in curves. The author points out that even the best of the water samples from this canal are very far from being potable, and he is of opinion that the self-purification of large streams contaminated with city sewage is exceedingly slow, and quotes his experience with the Hudson River water in support of this opinion. He took the precaution, when examining the water supply of Albany, to examine the river both above and below the place where the contamination entered, and although it showed a great improvement between the latter place and Albany, yet when comparison was made with the samples taken above the influx of contamination, the results led the author to condemn the river as a water supply. In another instance he traces an outbreak of typhoid fever in various cities using Hudson River water which had received contamination, whilst cities in the immediate proximity and using Hudson River water taken above such contamination were practically exempt from the outbreak.—D. A. L.

PATENTS.

Improvements in the Method of and Apparatus for Treating Towns' Slaughter-house and other Refuse or Substances or Materials. R. Cunliffe and E. Barlow, Manchester. Eng. Pat. 19,967, December 8, 1890.

The invention consists chiefly in filtering off any solid matter or sludge, or cutting up any animal refuse before subjecting to heat and destructive distillation. The hot gases are withdrawn and burnt; the residue is discharged. The special apparatus, figured, is claimed.—L. de K.

Improvements in Means or Apparatus for Sterilising Water. J. Y. Johnson, London. From "La Société Générale, Herscher and Co.," Paris, France. Eng. Pat. 2051, February 4, 1891.

This invention relates to an apparatus for completely sterilising water under pressure, so as to avoid the loss of the dissolved gases on which its palatability depends. The apparatus is complete in itself and is arranged to work continuously. The water to be sterilised is forced by a steam pump successively through two closed cylinders, each of which is provided with a coil through which hot and already sterilised water circulates. The latter is thus cooled down, whilst at the same time the fresh water in the outer cylinders is fore-warmed. The water then passes on to a sterilising vessel in which it is heated to 120°—130° C. by means of steam pipes and a steam coil supplied with steam from a small boiler. Subsequently the water passes through a filter, and finally is cooled by its passage through the cooling worms mentioned above. The sterilised water leaves the apparatus by a valve-tap which opens at a suitable pressure. The various valves, &c., are so arranged that the pump automatically ceases working until the water in the steriliser has attained the right temperature; or whenever the boiler pressure falls below a certain limit.—H. T. P.

Improvements in the Disinfection and Deodorisation of Sewage, and in the Apparatus for Preparing and Applying the Disinfectant. A. McDougal, Southport, and J. J. Meldrum, Manchester. Eng. Pat. 2846, February 17, 1891.

The prejudicial and offensive products of the decomposition of sewage matter are mainly compounds of sulphur and phosphorus with hydrogen and sulphur, or phosphorus compounds with alkalis, or ammonia. Sulphurous acid decomposes these products with the formation of odourless products, such as hypophosphites or thiosulphates, and on this fact the inventors have based their process. The sulphur dioxide is generated by the combustion of sulphur, pyrites, or spent oxide in a suitable furnace, and as a rule the termination of the action of the gas is conveniently indicated by the change of the liquid from an alkaline to an acid reaction. The sulphurous acid is supplied to the sewage, &c. by a steam injector fitted to the furnace generating the gas.—L. de K.

Improvements in Apparatus for Purifying Water. F. C. Nunn, London. Eng. Pat. 4619, March 14, 1891.

This invention relates to Anderson's revolving purifiers in which water is brought into intimate contact with metallic iron under high atmospheric pressure. The improvement consists in forcing the air into the cylinder through a pipe passing through one of the trunnions. On entering it branches out into four or more perforated pipes running side by side in the form of a grid to the other end of the cylinder. The air escaping from these pipes rises through the water to the top of the cylinder, and escapes through a pipe taken down and out through the other trunnion. The water is led out of the purifier through a long box with a perforated top, and suspended in a fixed position in the cylinder underneath the air pipes as low down as may be to allow the shelves to pass under it as the cylinder revolves. One end of the box is connected by a chamber

to the ordinary outlet pipe. The other box is closed so that the water cannot escape from the cylinder save through the box. The action will be readily understood. As the cylinder revolves, a large quantity of the purifying material is brought up by the shelves fixed in the cylinder and showered down on to the box, covering both box and air pipes and forming a heap by which means the bubbles of air are broken up. At the same time the water is thoroughly brought into contact with both the air and the purifying material on its way to escape through the box. The material is prevented from caking by the revolving of the cylinder.—L. de K.

Improved Process for Purifying Sewage Effluents and other Impure Liquids, and Apparatus therefor. E. E. Seruby, Epping. Eng. Pat. 5330, March 25, 1891.

THE invention consists in first removing as far as possible by the usual processes of settling, filtering, &c. all solid matters. By means of the inventor's apparatus the liquid is then saturated with oxygen, which may be generated in any suitable and convenient manner.—L. de K.

An Improved Mode of and Apparatus for Clarifying Muddy Liquids. R. Dervaux, Brussels, Belgium. Eng. Pat. 5340, March 25, 1891.

THE improved apparatus described is intended to facilitate the deposition of suspended particles from muddy liquids. It consists of a number of superimposed chambers, separated from each other by slanting or conical partitions. The water to be clarified is charged into these chambers from below, either from a common main or by means of separate supply pipes. The mud which settles out passes through holes in the centre or near the lower edge of each partition, to the bottom of the apparatus; whilst the clear liquid flows from the top of each compartment into a vertical collecting pipe. Finally, if necessary, the liquid is forced upwards through a filter, and thus further clarified. Details and drawings of various forms of the apparatus are given.—H. T. P.

A New or Improved Filter-Pump. H. Nordmeyer, Breslau, Germany. Eng. Pat. 7155, April 25, 1891.

See under L., page 422.

Improvements in Apparatus for Purifying or Treating Water. E. Devonshire, London. Eng. Pat. 11,735, September 1, 1891.

THE invention relates to apparatus for purifying water by bringing it into intimate contact with iron "or other chemically acting material," and aerating the water, and especially for "producing uniform contact between all the water and the purifying material, and air or gas." The invention consists in a vessel, chamber, or tank having a water inlet and outlet and grids or open-work partitions at intervals in the chamber with means for polishing them.

An elaborate description of the apparatus is given, but it cannot be well understood without the accompanying drawings.—L. de K.

Improvements in the Disposal of Sewage, and Apparatus connected therewith. J. Norris, Egham. Eng. Pat. 20,726, November 28, 1891.

THE inventor proposes a new method for the disposal of sewage without the ordinary cesspool, and for the prevention of the accumulation of sewer gas. A chamber called the fresh air inlet chamber has its sides and ends lined with glazed bricks. Its slopes at the bottom are of concrete, lined with white glazed tiles, and at the bottom is an enamel overflow pipe to carry off the liquid portion of the soil. The chamber is covered in by a hinged iron grating. The soil drain from the water-closet enters the chamber about one foot from the bottom. Underneath its orifice

is placed a strainer, the sides and ends of which are made of galvanised iron wires about $\frac{1}{2}$ in. apart, the top of the strainer being open. The bottom of the strainer is made of galvanised sheet iron punctured all over with holes of about $\frac{1}{2}$ in. in diameter, and turned up about 2 in. all round. A handle is fitted to the strainer so that it may be daily taken out and replaced, and it is also kept in its proper position by means of two iron rods. When the soil enters the strainer, its solid portion is retained, but the liquid portion passes into the chamber and is carried off by the overflow pipe. The solid contents should be daily removed and mixed with earth. A current of fresh air passes through the iron grating of the inlet chamber through the soil drain, which is connected with an ordinary ventilating shaft.—L. de K.

A New or Improved Method or Process for Purifying Sewage or Foul Waters. J. T. Wood, Rochdale. Eng. Pat. 22,747, December 30, 1891.

ACCORDING to this process, sewage is purified by subjecting it, in a finely-divided state, to the action of a current of air, air and oxygen, ozone, or other suitable gas. In practice the sewage to be treated flows through a screening chamber, and from thence passes over a suitable distributing mechanism into an oxidising chamber. During its descent into the latter, the sewage encounters a blast of air, &c. under pressure, with the result that it is converted into spray and becomes saturated with the gas. At this stage, any chemical precipitant that it is desired to add is projected into the spray by means of a hopper with revolving rollers. Subsequently the sewage flows into tanks where the suspended matters are allowed to settle. The clear supernatant liquid is then further purified by passing it over an "oxidising stairs" the "risers" or "faces" being provided with openings which communicate with tubes conveying air, &c. under pressure. It is claimed that by this process the oxidation will be more vigorous and complete than by any other means, that it will require less area for its operation, and can be applied indiscriminately in all cases. Modifications of the air-blast process, applicable to filter-beds and to weirs of rivers, are described. For details and drawings of the apparatus the original specification must be consulted.

—H. T. P.

(C).—DISINFECTANTS.

PATENTS.

Improvements in Supplying Disinfectants to the Flushing Pipes of Urinals, Water-Closets, and the like. T. Panario, London. Eng. Pat. 4287, March 10, 1891.

BY this invention simple and efficacious means are provided whereby disinfectants can be supplied to the flushing pipes of urinals and water-closets in a definite quantity. Various disinfectants can be used in and with the apparatus. Any solid disinfectant soluble in water, such as permanganate of potash, or any heavy liquid such as carbolic acid may be employed. The disinfectant is put into a receptacle which is tightly attached to the outer end of an elbow block in a preferably vertical position. When a flush is given, the rush of water will create a vacuum and so draw a portion of the disinfectant from the receptacle and cause it to mingle with the water.—L. de K.

A New or Improved Manufacture, being a Disinfectant, Antiseptic, Deodoriser, Vermin and Insect Destroyer, and also applicable for use as an Ingredient in and as Fire-lighters. A. Lutschannig, Liverpool. Eng. Pat. 4352, March 11, 1891.

THE leaves (needles) and young branches or shoots of pine or other resinous trees are broken, shredded, and dried, or pulped or otherwise reduced to a small condition and dried. If desired the material may further be teased and the dust separated from it by sifting. This preparation constitutes a valuable disinfectant for sick rooms, hospitals or similar places. When desired it may be

mixed with other disinfectants. It is also a good vermin or insect destroyer, and the inventor particularly recommends to spread it over the floors of dwelling rooms before sweeping these. In the application of the substance as a fire-lighter it must be mixed with an equal weight of rosin or like inflammable material. After melting the mixture it must be moulded by pressure into blocks of suitable form and size.—L. de K.

Improvements in the Method of Vaporising Carbolic Acid and other Disinfectants, and in Apparatus therefor. C. Scott, Belfast. Eng. Pat. 9083, May 29, 1891.

For the purpose of disinfection, carbolic acid or any other volatile disinfectant is subjected to the action of heat in a vessel having a large surface internally and a small bell-shaped mouth or aperture to admit the disinfectant and allow the vapour thereof to escape, by which means large quantities of the disinfectant volatilise in a moderate space of time.

After the vessel has been placed in the fire and made red hot it is removed into the room where the persons, animals or their belongings are to be disinfected, and after external air has been as far as possible excluded, the carbolic acid is poured into the vessel.—L. de K.

Improvements in and relating to Soluble Quinoline Antiseptics. A. Lembach, U. Schleicher, and C. J. Wolff, Biebrich, Germany. Eng. Pat. 18,913, November 3, 1891.

It has been proved that quinoline and toluquinoline possess great antibacterial properties, but the complete insolubility of these substances in non-acid fluids presented a serious obstacle to their becoming available for general use.

The inventors have at last succeeded in finding a suitable solvent, and there is now nothing in the way of the technical and commercial application and use of the said substances as antiseptics. The invention consists in using soap in the nascent state. For instance, to 50 kilos. of a suitable oil, such as castor oil, is added 50 kilos. of quinoline, and also 15 kilos. of hydrate of potash in 50 kilos. of water. The mixture is boiled until the saponification is quite complete, which stage is indicated by the perfect clearing of the liquid, which must then be diluted with another 85 kilos. of water.—L. de K.

Improvements in Candles or Tapers for Fumigating or Perfuming or Evaporating Purposes. J. Ryder, Manchester. From E. A. Weidemann, Liebenburg, Germany. Eng. Pat. 22,742, December 30, 1891.

XIX.—PAPER, PASTEBOARD, Etc.

Determination of Mechanical Wood Pulp in Paper. R. Godeffroy. Mitt. k. k. Techn. Gew. Museums, 1891, 295.

See under XXIII., page 464.

On the Quantitative Determination of Mechanical Wood Pulp in Paper. J. Bandisch. Papier Zeitung, 1891, 16, 2414–2415.

See under XXIII., page 464.

Bisulphite Process: Boiler Tests. Papier Zeitung, 1891, 16, 2699.

The progress of the treatment in the digesters is best followed according to A. Harpf, by the results of the "ammonia test," precipitation of neutral sulphite, together with those of the iodine titration, of samples of the liquor withdrawn from time to time. Such purely empirical evidence as colour, smell, and viscosity are adopted by the "practical man" often as his only guide, and it must be admitted with satisfactory results.—C. F. C.

Straw Boiling. Papier Zeitung, 1891, 16, 2700.

In boiling straw for straw boards it is recommended to introduce the quicklime directly into the boiler: and in districts where only inferior lime is obtainable, a proportion of soda ash should be added. The mixed lime and soda boil is an economical variation of the ordinary treatment in the case of refractory straws, or where the supply of water for washing purposes is not abundant.—C. F. C.

On Cellulose and its Forms: Cellulose Gum. W. Hoffmeister. Landw. Versuchsstat. 1891, 39, 461.

THE author formerly held the view that the cellulose might be dissolved out of plant-tissues by dilute alkalis when certain substances, "incrustations" are removed; his present experiments prove that this is not exclusively the case. He confirms the observation, however, that the cellulose can be quantitatively extracted in the pure state on treatment with "chlorine mixture" and ammonia. By direct treatment gum-like compounds are obtained; whilst to isolate these previous extraction with soda-lye is necessary. They may also be obtained by treating the tissues with glacial acetic acid and ammonia in the warm; and by dissolution in ammoniacal cupric oxide solution, but the form of the cellulose undergoes alteration by these methods. The author names that form of cellulose which is soluble in caustic alkali in accordance with Tollens' proposal "cellulose gum." This has, however, various forms which may be spoken of collectively as cellulose gum-like substances. To prepare "cellulose gum" in the pure state the raw material is necessarily extracted with ether, alcohol, water, and dilute ammonia; the residue is either extracted with ammoniacal cupric oxide solution to separate the cellulose from the lignin, or when this is not needful digested direct with dilute ammonia on the water-bath. If starch be present it is removed by digestion on the water-bath with glacial acetic acid and a few drops of hydrochloric acid, or better still with malt extract. After digesting the residue for a long time with ammonia and washing it, it does not give the lignin reaction, but this substance is still present. The cellulose is then extracted with ammoniacal cupric oxide solution, more or less "cellulose gum" can then be separated from the cellulose thus obtained, by extraction with 5 per cent. soda-lye. Hard woods may be initially extracted with hot glacial acetic acid. The "incrusting substances" or their decomposition products may be obtained from the glacial acetic acid and ammoniacal extracts. A. R. L.

The Influence of Moisture on the Vegetable Sizing of Paper. P. A. Hasselkuss. Chem. Zeit. Rep. 1891, 15, 326.

THE more humid the air is during the sizing of paper the less successful is the operation; slow drying is better than quick. It cannot be stated for all descriptions of paper beyond what limit of humidity deficient sizing is produced. There is however for all kinds of paper a certain maximum, and the thicker the paper is the more water can it take up without deleterious influence on the sizing; 5–8 per cent. may be placed as an average amount of water for paper to contain. When paper is sized in a too moist condition its defects can be remedied by keeping it for three weeks to three months in dry air; whereas even a well-sized paper

is spoiled by keeping it in a damp room. The alternating action of dry and moist air (containing more than 80 per cent. of moisture) appears to be exceedingly harmful. Paper containing a large quantity of "cellulose or straw-pulp" is not affected by moisture, i.e., as regards its sizing.

Letter or post-card paper which require well sizing, and where the tinting is not of so much importance, should contain 15—30 per cent. of "cellulose or straw-pulp." Better and more durable papers to which the addition of "cellulose" is inadmissible should only be stored in dry rooms.

—A. R. L.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

On "*Phenocoll*," an Antipyretic and Antirheumatic. Schmidt. Pharm. Zeit. 1898, 36, 585.

(1) (4)
 "*Phenocoll*," $(C_2H_5O)_6C_6H_4 \cdot (NH \cdot CO \cdot CH_2 \cdot NH_2)_2$, is prepared by treating *p*-phenetidine with acetyl chloride, whereby chlorophenacetine is produced, and then treating this product with ammonia. It has the antipyretic properties of phenacetine, while by reason of its superior solubility and better resorption, its action is more prompt. It is a monacid base; the acetate forms interlaced needles, and is soluble in $3\frac{1}{2}$ parts of water; the salicylate crystallises from water in long needles, and combines the therapeutic properties of phenocoll and salicylic acid. The following tests are given for the hydrochloride:—0.5 grm. dissolves to a clear solution in 15 cc. of water, which should not give a reaction with red litmus paper; on addition of caustic potash a white crystalline precipitate of the base separates; it leaves no residue when ignited on platinum foil. When the base is heated with a little water it melts, but resolidifies to a crystalline mass on cooling.—A. R. L.

On *Pental*, C_5H_{10} , an Anæsthetic. Holländer Therapeut. Monatsh. 1891, 5, 509.

PENTAL is the name given to the amylene $CH_3 \cdot CH_2 \cdot C(CH_3)_2$ boiling at 38° . It is prepared by heating "amylene hydrate" with acids, and is a colourless liquid, which is insoluble in water, but miscible in all proportions with alcohol, chloroform, and ether, and is extremely volatile; when inhaled it does not in any way injure the mucous membrane of the mouth and breath passage. The narcosis produced by pental comes on by degrees, and headache or vomiting are not produced during the narcosis nor afterwards; the author could observe no effect either on the heart's action or on the respiration. It acts quicker than chloroform, and it has the advantage over "bromether" that the narcosis lasts longer, that unpleasant after-actions are not produced, and that even in large doses it appears innocuous.—A. R. L.

Lupanine. C. Leibeck. Arch. Pharm. 1891, 531.

LUPANINE from the blue lupin yields a hydrochloride of the composition $C_{15}H_{24}N_2O \cdot HCl + 2H_2O$.—D. A. L.

Sophorine. C. Plugga. Arch. Pharm. 1891, 561.

ACCORDING to the author, sophorine from *Sophora tomentosa* is presumably identical with cytisine.—D. A. L.

Atropine and Hyoscyamine. W. Schütte. Arch. Pharm. 1891, 192.

HYOSCYAMINE in solution, even in the form of auro salt, it is found is converted into atropine by repeated crystallisation, or by frequent evaporation, or by prolonged storage. In roots of young plants of *Atropa belladonna* hyoscyamine only is found; in those of old plants atropine is also found. The percentage of alkaloid varies according to the season.

	Percentage in Young Roots.	In Old Roots.
Spring.....	0.13	0.17
Summer.....	0.45	0.36
Autumn.....	0.46	0.28

The leaves contain besides a little atropine much hyoscyamine. Atropine and hyoscyamine are both found in the ripe berries of cultivated *Atropa belladonna nigra*, but in the berries of the wild plant atropine only is found; the ripe fruit of the yellow atropa also only contains atropine, whilst the unripe fruit of the wild black nightshade, the leaves of both the yellow and black wild plants and both fresh and old seeds of *Datura stramonium* contain principally hyoscyamine with a small quantity of atropine. *Datura stramonium* seeds also yield a small quantity of skopolamine.—D. A. L.

Further Researches on Ash-free Albumen. E. Harnack. Ber. 1892, 24, 204—209.

THE author has succeeded in preparing a form of albumen which differs in many respects from the modifications hitherto described. It is prepared by treating an alkaline albumen solution (free from corpuscles) with copper sulphate solution, re-dissolving the filtered precipitate in a little alkali (soda), and re-precipitating with dilute acetic acid, decomposing the precipitate with strong caustic potash solution, and after allowing the solution to stand for 24 hours it is treated with excess of hydrochloric acid, and the precipitate is washed. When the excess of hydrochloric acid is removed the substance becomes soluble in water, is free from ash, but still retains from 1 to 2 per cent. of hydrochloric acid, which can be removed by dialysis. As the last portions of acid leave the albumen solution, it becomes a transparent jelly, which on boiling with water becomes compact and white with a crystalline appearance and character, especially on drying. Alcohol brings about a similar transformation of the jelly. The crystalline powder is insoluble in pure water, but dissolves at once on the addition of a trace of hydrochloric acid. An excess of the acid would re-precipitate the albumen from this solution. The dialysed substance is of course soluble in presence of a trace of free alkali. The change produced by boiling seems to be a transformation of the colloid into the crystalline modification, but the question whether changes have thereby taken place in the albumen molecule must be left for further elucidation. The possibility of the soluble hydrochloric acid compound being identical with acid albumen is negatived on a comparison of their reactions.

	Acid Albumen.	Ash-free Albumen.
In water.....	Not soluble	Soluble.
In dilute hydrochloric acid...	Soluble	Not soluble.
On adding alcohol ether, &c. to the solution.	Precipitated	Not precipitated.
On adding excess of hydrochloric acid to the solution.	Not precipitated	Precipitated.
On adding neutral salts to the solution.	Partially precipitated.	Precipitated.

On the Testing of Liquor Ammoniac. J. Hertkorn.
Chem. Zeit. 1891, **15**, 1493.

See under XXIII., page 457.

Researches on Digitalin. J. Houdas. Compt. Rend.
1891, **113**, 648—651.

THE existence of this substance which is characterised like saponin by the property of causing water to froth, was first noticed in the *Digitalis* by Horndle and Quevenne in 1840. It was isolated by Walz in the amorphous state (Jahresh. f. prakt. Pharm. **14**, 20), and has been studied by Nativelle (Journ. de Pharm. et Chim. **20**, 81), Goerz (Dupat thesis, 1873), Kausmann (Journ. de Pharmacie, **20**, 427), and finally by Schmiedeberg (Arch. f. Experiment. Pathologie, **3**, 16). Schmiedeberg admits the existence of two digitalines soluble in water, which he calls *digitouin* and *digitalin*. The author showed in a memoir read before the French Academy of Medicine in 1891 that Schmiedeberg's products consist almost entirely of one substance, for which he keeps Nativelle's name, *digitalin*. The aqueous solution obtained in the preparation of digitalin was treated with absolute alcohol according to Schmiedeberg's directions, and then fractionally precipitated with ether. The precipitates, after repeated fractionation, yielded the same body as that precipitated by absolute alcohol. Digitalin cannot be crystallised from an aqueous solution, but if an alcohol of the fatty series, e.g., methyl, ethyl, or amyl alcohol be added to this solution a crystalline compound of hydrated digitalin and the alcohol is obtained. The solubility of the crystals thus found decreases as the molecular weight of the added alcohol increases. If amyl alcohol be added to a concentrated solution of digitalin, the solution rapidly crystallises out if the solution be sufficiently concentrated the mass may become solid. Phenols act in the same way as alcohols. Digitalin crystallised from ordinary alcohol is obtained in the form of fine needles radiating from a centre, which lose their alcohol and water of crystallisation at 110°. Digitalin is slowly soluble in cold, rapidly soluble in hot, water; the solution froths on agitation, and on evaporation yields a glassy mass. It is a glucoside. It is only slightly soluble in absolute alcohol, and almost insoluble in chloroform, ether, and ligron. The aqueous solution is levo-rotatory $[\alpha]_D^{25} = -49.25^\circ$. On heating the substance it does not distinctly melt; about 250 degrees it agglomerates; at 270°, froths; at 280°, is converted into caramel. It appears to be unalterable in the air, both in the solid and dissolved states. It is soluble without colouration in cold hydrochloric acid, and the solution on heating turns to a red violet colour with a slight green fluorescence. With sulphuric acid diluted with an equal bulk of water it gives a yellow colouration in the cold which turns first red then black on heating. The solution yields a precipitate with tannin and ammoniacal lead acetate. Analysis suggests a formula $C_{31}H_{52}O_{17}$, but this can only be looked on as tentative until the decomposition products are better known. The author rejects Kiliani's formula (Ber. **23**, 1555, and **24**, 339; this Journal, 1890, 820; and 1891, 567) $C_{27}H_{44}O_{13}$. By cautiously acting on digitalin with dilute acids it has been split up into two new glucosides without any liberation of glucose. These products and a new glucoside derived from the amorphous digitalin of the Codex will be described shortly.—P. J. H.

Coca Leaves. J. Holmes. Chem. and Druggist, **40**, 580.

IN commerce there are two kinds of leaves, the dark green, strong Bolivian, or Huanoco, and the light green, Peruvian, or Truxillo leaf. A third variety of leaf is that cultivated in the island of Java, which is occasionally met with in the markets of the world, and has the reputation of being a very carefully dried article. About four years ago Mr. Morris, of Kew, in an exhaustive paper on coca, described a variety which he called "Novogranatense," which has narrower leaves and is of a paler green colour than the Bolivian leaf, and this is the variety which appears to yield the

Java leaf of commerce. With regard to the respective alkaloidal values of the various leaves, Peruvian and Bolivian leaves yielded cocaine and isotropyl-cocaine in almost equal parts, whereas the Java leaves gave less cocaine than the two former. In this country, cocaine was generally prepared by purifying the crude cocaine manufactured in Peru, and the Java leaves were therefore all used by the German cocaine makers. So far as cocaine manufacture is concerned the leaves of the *Erythroxylon Bolivianum* are preferred, and of this variety the pale brown leaves are the best. The leaves of young plants contain more than double the quantity of alkaloid found in the leaves from old shrubs, and moisture caused a considerable loss in the yield of alkaloid. The variety described by Mr. Morris tapers at the base and the flowers have a short stigma. The cultivated Java leaves are not so long as Mr. Morris's "Novogranatense" leaf. They are broader in the middle, the flowers have longer stigmata, and the habit is different from that of the others. The brown Bolivian leaf, finally, has a more leathery appearance and the midrib shows a distinct ridge.

Cinchona. J. Holmes. Chem. and Druggist, **40**, 580—581.

At a meeting of the Pharmaceutical Society nine varieties of bark were exhibited and described. Mr. Thomson, a Colombian planter, had discovered some of these barks in the central range of the Colombian Andes while travelling in that region a few years ago; others were cultivated by him upon his plantation. Analyses of the barks showed them to be of remarkable average richness, the following being the figures given:—

	Quinine Sulphate.	Quinine.	Cinchonidine.	Cinchonine.	Quinidine.	Amorphous.
Thomsoniana	5.94	4.45	0.27	0.82	0.26	0.74
Ledger Verde	4.90	3.68	0.00	0.01	0.20	0.44
Negra	7.30	5.48	0.00	0.10	Trace	0.78
Morada	3.06	2.30	0.00	0.04	0.50	0.38
Tuna	9.04	6.18	0.40	0.38	0.18	0.42
Pombiana...	5.88	4.41	0.34	0.02	Trace	.26
Orcinalis....	6.32	4.74	1.23	0.10	0.07	0.42
Succirubra .	5.93	4.15	2.77	0.12	0.02	0.36
Hybrid	3.32	2.49	1.92	0.04	Trace	0.52

The three last named kinds are well-known varieties, and not natives of Colombia, any more than the Ledgeriana Verde and Morada. The tree yielding the bark marked "Negra" was discovered by Mr. Thomson in 1883. It grows at an altitude of 8,000 feet, attains maturity with singular rapidity, resembling, in this respect, the Succirubra variety, and is exceedingly rare. Both flowers and leaves are very large; the latter have a rich brown colour and hairy undersurface. They are without the scrubby leaves, or little warts, the existence of which has been held to indicate alkaloidal richness. Whether, as a matter of fact, rich barks are always collateral with scrubby leaves may be doubted. The microscopical structure of the *Negra* bark indicates a relationship to that of the *Lancifolia*. The tree grows slowly and does not appear to prosper so well under cultivation as in the wild state. It received from Mr. Thompson the name of "Negra" (black), because of its deep claret-coloured petioles, by which the peons are able to distinguish it from other kinds. In the Tuna bark ("tuna" is a native word of uncertain meaning), the richest of all Mr. Thompson's varieties, the resemblance to the Ledger species is very evident. Like all other kinds belonging to the *Lancifolia* group, the bark of this species contains numerous stone cells, fairly well distinguishable under the microscope; in the soft or middle layer there are no stone cells; in the other layers the cells are now arranged in solitary lines, now in clusters. The Pombiana variety was discovered in 1883 in Ecuador by a

gentleman living in that country, and whose name had been given to it. The *Pombiana* does not in histological structure resemble any of the cinchonas, but it is like the myrtaceous plants. Its leaves are small and glossy, and its foliage is very dense. The capsules also are small (a fact which, in cinchonas, is held to presage richness in quinine). The wood fibres form distinct oblong groups like those of the *C. lancifolia*, the leaves are leathery and narrower than those of the *C. pitayensis*, the flowers are hairy on the under-surface of the corolla, the petals are hairy all over, whereas in nearly all true cinchonas the petals are only fringed with hair. In *C. pitayensis* there are no stone cells in the middle layers of the bark. The *Pombiana* may be said to form a link between the Pitayo and the *Lancifolia*, or "soft Colombian," species.

Eucalyptus Oil. J. Holmes. Chem. and Druggist, 40, 581.

THE author referred to the introduction of *Eucalyptus Globulus* oil, and the great differences which were noted in the qualities of commercial oils as soon as eucalyptus began to be popular. Within the last two years a new kind of oil had appeared in the market under the name of *E. oleosa*, which had a cuminalike odour, very different from that formerly known as *oleosa* oil. The fact was that the oil which formerly went by that name was the Mallee scrub oil, a mixture distilled from four species which grew together, and the new *oleosa* is a distinct variety. He expressed the opinion that although the original reputation of eucalyptus oil was based on the *Globulus* variety, it had, in reality, happened that for years the *amygdalina* oil was the only one which came on the market, and even yet, this oil is preferred for inhaling in lung-diseases.

Artificial Salicylic Acid. Chem. and Druggist, 40, 590—591.

THE investigation completed about two years ago by Messrs. Dunstan and Bloch, and supplemented by Professor Charteris, left it somewhat uncertain as to whether artificial salicylic acid can be obtained absolutely identical with the natural product—at least, on a commercial scale. Apart from the work of these investigators, which undoubtedly served to call special attention to the salicylic acid question in this country, much has been done to show that a determination of the melting point of the acid is the best criterion of its quality, and it has been admitted that the boiling point figure, 155° C., is too low. In this connexion Messrs. Helbing and Passmore have just completed an examination of a well-known brand of salicylic acid and its sodium salts, the result of which, as published in "Helbing's Record," contains several interesting points. The investigators confirm previous observations, in stating that the melting point of the pure acid is slightly below 157° C.—to be exact 156·85°—156·86° C.—and they find that fractionation of the silver salt is the quickest and surest means of determining the purity of the acid, since any cresol derivatives which may be present accumulate and come out in the last fractions. In one respect, it is a matter of regret that Messrs. Helbing and Passmore were not dealing with a less pure acid than they had, for in the worst sample, melting at 156·4°—156·75°, the amount of impurity was only about 0·1 per cent., whilst Messrs. Dunstan and Bloch dealt with acids melting at 154° C., and the like. In fractional crystallisation with silver, a known weight of the acid is first converted into the sodium salt, and freed from carbonic acid by adding a trace of nitric acid, and boiling. During ebullition a 10 per cent. solution of silver nitrate is added in quantity sufficient to precipitate from a tenth to a fifth of the salicylic acid. Silver salicylate is practically insoluble in hot water, and, unlike lead salicylate, has no tendency to the formation of basic salt, a disadvantage which gave Messrs. Dunstan and Bloch much trouble, and to which is probably due the want of regularity in the melting points of their fractions. After the first fractionation with silver,

a second, third, and fourth, or even more may be made using increased quantities of silver nitrate until 50 or 60 per cent. of the acid has been precipitated, and then decreasing the size of the fractions. Much depends upon the initial melting point of the acid; should this be low, it is advisable to keep the larger fractions towards the end, so as to accumulate the impurities in them. The acid is regenerated from the silver salicylate by digestion with boiling water and an excess of hydrochloric acid, the mixture filtered, the salicylic acid crystallised twice and dried. The melting point of each fraction is then determined. In one case Messrs. Helbing and Passmore found four fractions from a "physiologically pure" acid melted at the same temperature, viz., 156·85° C., the residuum melting at 156·84° C. The sample was, therefore, "chemically identical with the natural acid from oil of wintergreen." As showing the delicacy of this method of testing, it is observed that the last fraction of another specimen (7 per cent. of the quantity taken) melted at 156·3° C., the others being normal, and the last of another (10·5 per cent.) melted at 155·9° C. As Fischer found that the presence of 1 per cent. of cresotic acids reduces the melting point of salicylic acid by about 1° C., it is obvious that these last fractions give a very critical indication of quality, especially when the initial melting points only vary from the normal by fractions of a degree. It is demonstrated then that silver fractionation ensures true separation of salicylic acid from its objectionable contaminants. Another point brought out by the investigation is that sodium salicylate in crystals is anhydrous, or practically so, the loss on drying at 104° C. being only 0·24 per cent., the boiling point formula ($\text{NaC}_6\text{H}_5\text{O}_3$), H_2O requiring 5·3 per cent. The loss of scale salicylate was 0·23 per cent. and of powder 0·19 per cent. The obvious conclusion is that sodium salicylate does not contain water of crystallisation, the little which there is present being mechanically retained after drying.

Safrol. Chemist and Druggist, 40, 592.

THE importation into Europe of the waste product, camphor oil, from the distillation of camphor in Japan, has turned out to be a veritable mine of industrial, if not monetary wealth. At first the oil had solely a medicinal application, but the study of its constituents resulted in the discovery of several valuable components. The most important of these is safrol—the sassafras-like body to which the peculiar odour of the oil is due. This was first isolated by Schimmel, and has since been used extensively to cover the odour of the fatty bases of soap. The discoverers report that the use of the article for this purpose is as great as ever, and that, mixed with citronella or cassia oil, it is also extensively employed, such mixtures being made more lasting by the addition of a little cedar-wood oil. One part of the mixture is sufficient to add to 1,000 parts of common household soap basis. Under the name of "safrine," safrol has been introduced in America as artificial oil of sassafras. The specific gravity (1·108) indicates its source; ol. sassafras, U.S.P., having a specific gravity about 1·090.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

The Chemical Changes attending Photographic Operations. H. E. Armstrong. Chem. News, 65, 181—184.

THE author describes the electrolytic action of the De La Rue-Müller cell and compares it with the similar action which attends development. He discusses the influence of bromide as a restrainer, and the accelerating effect of alkalis. In the case of ammonia being used as the accelerator, the addition of bromide prevents the solution of silver bromide in the ammonia; and the image is probably not

composed entirely of silver, but of a species of pigment, possibly formed by the dissolved silver and the colouring matter from the oxidised developer, to which also the formation of the peculiar fog which often occurs with ammonia and pyro-developers may be attributable. In the case of alkalis being used as accelerators, the bromide has a different action, probably that of neutralising the hydrobromic acid formed and thus preventing the reversal of the action which would otherwise take place. Also, as a silver haloid in the presence of an alkali and reducing agent tends to undergo reduction, the accelerating effect of adding alkali may be understood, as well as the restraining influence of bromide which tends to reverse the action. The author, contrary to Meldola's view, suggests that the invisible image is not the same as the darkened product formed on development, i.e., an oxyhaloid compound of silver; that there are perhaps two latent images formed, one by the blue and the other by the yellow rays, these behaving differently during development. The blue image being silver and the yellow silver oxyhaloid, the former being comparable with the silver wire in the De la Rue-Müller cell, whilst in the case of the latter the silver bromide undergoes electrolysis in a circuit which includes oxygen, the halogen which is liberated converting the silver formed by the action of the blue rays into silver haloid; but in gelatin plates this halogen is taken up, still after a time depending on the exposure, the gelatin will become saturated, and the silver would tend to become rehalogenised; this view being borne out by the phenomena of over-exposed plates flashing out on development, owing to the richness in oxyhaloid. If sufficient bromide was present the oxyhaloid may be converted into haloid, and so the flashing out prevented. Finally, the author compares the sensitiser to oxygen as influencing the solution of copper in sulphuric acid.—J. C. C.

PATENT.

Improvements in Photographic Printing Processes. W. W. J. Nicol, Birmingham. Eng. Pat. 7312, April 28, 1891.

THE use of silver salts for the developing mixture described in the inventor's previous patent (this Journal, 1890, 413) is connected with certain inconveniences. In order to obviate these, the silver solution is employed for the preparation of the sensitising solution, along with suitable proportions of certain organic iron salts (citrate, oxalate, or tartrate), and if desirable, with the potassium and ammonium salts of these acids. The material thus prepared is exposed to light under a screen and the ferrous image then developed with an alkaline salt of carbonic, acetic, or any other of the above enumerated organic acids. In certain cases addition of potassium chromate will be necessary. The resulting prints are washed in dilute ammonia and finally in water.

In an alternate method the print may be developed at once with dilute ammonia, which may hold in solution any of the enumerated developing salts.

In a third method the paper may be prepared with a mixture of ferric salt, silver salt, and a developing salt; the sensitised surface is then exposed to the action of the light and the print washed in ammonia.—H. A.

XXII.—EXPLOSIVES, MATCHES, Etc.

PATENTS.

Improvements relating to the Manufacture of Nitro-substitution Compounds of Cellulose. H. Maxim, Crayford. Eng. Pat. 4129, March 7, 1891.

The object of this invention is to produce nitrocellulose of a high grade with a less consumption of acids than has hitherto been necessary. In carrying out the invention two immersion baths are employed, the first containing the

usual mixture of strong acids. In this, the cotton is immersed for 5–6 minutes and conveyed with about six times its own weight of acids to the second bath, which contains a large excess of slightly weaker acid mixture. The partially nitrated cotton remains for 16–48 hours in this bath until the nitration is completed, and the large excess of acids prevents any fuming off through heating. The strength of this second bath is maintained by the portion of stronger mixture introduced with each batch of cotton from the first.—W. M.

New or Improved Explosive Compositions. E. von Brank, Boppard-am-Rhein, Germany. Eng. Pat. 5027, March 20, 1891.

This invention relates to the manufacture of powders containing potassium chlorate, for shooting and blasting purposes. The composition of the powders is as follows:—

SHOOTING.

Potassium chlorate.....	100 parts.
Boiled linseed oil.....	40 parts.
Lead oxide.....	1·5 parts.

BLASTING.

Potassium chlorate.....	100 parts.
American resin.....	15 parts.

In the blasting powder the ingredients are mixed to a stiff paste with a decoction in water or vinegar of a gum-giving plant, the mass being afterwards dried and granulated.—W. M.

Improvements in Explosives. C. H. Curtis, London, and G. G. Audriè, Dorking. Eng. Pat. 5821, April 4, 1891.

THE object of this invention is to obtain an explosive the explosiveness of which can be regulated at desire, and at the same time to render it proof against atmospheric changes, and producing greater cohesion between the fibres. Gun-cotton or other nitrocellulose compound is taken wet and treated with a warm solution of gelatin, whereby its fibres or particles become coated with a thin film of gelatin. The material is then further treated with tannic acid for the purpose of rendering the film of gelatin insoluble and imputrescible.

The thickness of the film should be such as to increase the weight of the nitrocellulose about 5–10 per cent. according to the degree of explosiveness desired.—W. M.

Improvements in the Manufacture or Production of Gun-powder or like Explosives. J. Y. Johnson. From "The Dynamite Actiengesellschaft Nobel," Vienna, Austria. Eng. Pat. 6129, April 9, 1891.

THE object of this invention is the manufacture of a smokeless powder from nitrocellulose without the addition of substances which dissolve or gelatinise the nitrocellulose. Nitrocellulose in a state of fine meal is mixed with di- or tri-nitro derivatives of benzene, toluene, xylene, or naphthalene, the proportions of nitrocellulose to the said nitro-derivatives depending on the projective force required, varying from 99 to 70 parts by weight of the former to 1 to 30 parts by weight of the latter.—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Spirit Blast-Lamp. Chem. Zeit. 1891, 15, 1494.

The lamp consists of a brass reservoir or kettle with a copper bottom, and is filled with commercial spirit. The side tubulus terminates with a safety valve. A small quantity of spirit is placed in the dish under the kettle and ignited, whereby the spirit contained in the kettle is boiled and its vapour escapes by two tubes, one terminating at the bottom

SPIRIT BLAST LAMP.

of the kettle, and the other having the form of a Bunsen burner extending from the top portion of it. The vapour escaping from the lower tube is ignited by the flame from the dish, and it serves to keep the evolution of vapour continuous. On now igniting the vapour escaping from the upper tube, a flame resembling that of a Bunsen burner is produced, which melts 2 mm. copper wire with ease, and brings 1 litre of water to the boiling point in eight minutes. The two flames are regulated by cocks shown in the Figure.

—A. R. L.

INORGANIC CHEMISTRY.—
QUANTITATIVE.

On Volumetric Estimations and Methods of Separation by Means of Potassium Ferro- and Ferriyanide.
C. Luckow. Chem. Zeit. 1891, 15, 1491—1492.

In the titration of zinc with potassium ferriyanide any iron present must be previously removed as ferric oxide, or the titration must be made in an ammoniacal solution, the iron having been previously oxidised to the ferric state; certain metals, however, as, for example, silver, do not form ferriyanides insoluble in ammonia. The author finds that many metals may be titrated with potassium ferriyanide in acid solution, even in the presence of ferric salts, and that with the exception of gold, platinum, antimony, and arsenic, those metallic salts which do not form insoluble compounds with the ferriyanide may be estimated with the ferriyanide, these are mercuric, ferric, manganic, uranic, stannic, and lead salts. For the estimation of zinc and lead in the presence of one another, the former is titrated in a solution acidified with nitric or acetic acids with ferriyanide (the zinc ferriyanide may also be weighed), and the latter in the filtrate from this with ferriyanide. Stannic oxide is evaporated with oxalic acid, the solution acidified with dilute sulphuric acid and estimated either gravimetrically or volumetrically with ferriyanide, the separation from antimony and arsenic being thus effected. The ordinary impurities in commercial potassium ferriyanide—chlorides, sulphates and sodium salts—need only be removed in dealing with such metallic salt solutions as precipitate them. The solution of the ferriyanide undergoes slight changes in direct sunlight; whilst the ferriyanide is influenced both in the dry state and in solution by temperature and light. In recrystallising the latter the temperature should not be raised above 50°—60°, and the solution is cautiously treated with chlorine to oxidise any ferriyanide produced; it should not give a precipitate with lead salts.

The indicators, which cannot be added to the solution, may be either such as react with the metal or with the precipitant. Of the former kind a mixture, zinc salt, ammonia, ammonium sulphide, and rosolic acid, is conveniently employed with those metals forming dark sulphides, it being easy to determine the complete precipitation of the metal by the appearance of the rosolic acid colour in the place of the sulphide; whilst of the latter kind copper acetate solution acidified with acetic acid or ferric chloride is used for ferriyanide, and cobaltous, or better, ferrous salts for ferriyanide.—A. R. L.

On the Testing of "Liquor Ammoniac." J. Hertkorn.
Chem. Zeit. 1891, 15, 493.

ACCORDING to the German Pharmacopœia "spirits of ammonia" should only give a slight turbidity on addition of an equal volume of lime water. When, however, a current of carbonic anhydride is passed over the surface of this liquid or it is allowed to remain in the presence of carbonic anhydride, it frequently still only gives a slight turbidity with lime water which cannot be removed by filtration; if, however, the liquid be boiled a copious white precipitate falls. Since this cannot be due to the presence of ammonium carbonate, the author ascribes it to the formation of ammonium carbamate which also pre-exists in the solution; this compound, as is known, breaks up on heating into ammonia and carbonic anhydride. Commercial ammonia solution (100 cc.) sp. gr. 0.921 was diluted with an equal volume of water (free from CO₂), lime water (200 cc.) added, and the mixture placed aside for an hour, when it was slightly turbid. On boiling the mixture for one hour 0.031 grm. CaCO₃ was precipitated, and the same quantity when the ammonia solution was boiled alone for an hour and the lime water subsequently added. As such an ammonia solution might on the above given official test be taken as free from carbonic anhydride, and used for determinations which are vitiated by its presence, the author recommends that the directions of the German Pharmacopœia for the testing of "liquor ammoniac" be altered to the following:—"A mixture of equal parts of spirits of ammonia and lime water should only show a slight turbidity after boiling."—A. R. L.

On the Estimation of Manganese by the Chlorate Method.
W. Hampe. Chem. Zeit. 1891, 15, 1579—1580.

A COMMITTEE appointed by the "Verein von deutscher Eisenhüttenleute" recently stated in their report on the estimation of manganese (Stahl und Eisen, 1891, 11, 373) that the chlorate method devised by the author (Chem. Zeit. 1883, 7, 1106; 1885, 9, 1083 and 1513; this Journal, 1885, 690) only gives good results when used in a modified form, and when the titre of the solutions are determined exactly as the actual titration is carried out. The author contends, and gives most cogent reasons, that the proposed modifications add nothing to the accuracy of the method.—A. R. L.

Quantitative Analysis of Sulphides. P. Jannasch and V. Wasowicz. J. Prakt. Chem. 1892, 45, 94—102. (See also this Journal, 1890, 769.)

This paper gives an account of the working out of a method for analysing quantitatively molybdenum glance, realgar, and orpiment; in the determination of the sulphur ignition in oxygen is effected and the sulphur dioxide formed is collected, not in bromine water as usual, but in hydrogen peroxide solution.

Analysis of Molybdenum Glance.—The finely powdered mineral was heated in a platinum boat in a current of oxygen, and the evolved gas was bubbled through a three per cent. solution of hydrogen peroxide (free from sulphuric acid), contained in three flasks, or better, two flasks, and a cylinder as the final vessel, the cylinder being merely a check, need not contain so much peroxide as the others

The combustion lasted an hour and a half, an excessive temperature having to be guarded against to prevent the possibility of sublimation of molybdic acid.

The boat was removed from the combustion tube while still hot and the contents found to be, as is necessary, perfectly white. When cold the boat and its contents, which were proved to be free of sulphuric acid, were weighed, and then warmed on a water-bath for an hour with ammonia in a porcelain dish; the reddish insoluble residue was filtered off and washed with ammonia, and finally with ammoniacal water. To the filtrate (after heating for some time on a water-bath to remove ammonia) a solution of mercurous nitrate was added; the precipitate was filtered off after 24 hours, washed with a very dilute solution of mercurous nitrate, then dried at 110°C ., and as completely removed from the filter-paper as possible. What remains on the paper is dissolved by extremely dilute nitric acid and run into a Rose's crucible in which it is taken to dryness on a water-bath, after which the dried precipitate previously removed from the paper is added, and the whole reduced to metallic molybdenum in a current of hydrogen, heating being at first performed by a Bunsen flame, afterwards by aid of the blow-pipe. Complete reduction occupied two hours.

The reddish residue insoluble in ammonia was shown to contain merely oxide of iron and silica; the iron was removed by sulphuric acid and precipitated by ammonia.

For determination of the sulphuric acid the hydrogen peroxide solutions were evaporated on a water-bath to small bulk, a few cc. of dilute hydrochloric were then added, and the sulphuric was precipitated with barium chloride in the usual way.

A number of results obtained show close agreement with each other.

Analysis of Realgar and Orpiment.—These were burnt in oxygen as in the foregoing case of molybdenum, and the products passing away were bubbled through hydrogen peroxide. The hydrogen peroxide was subsequently evaporated to a smaller bulk on a water-bath, and then excess of ammonia was added and magnesia mixture free from sulphates. The whole was allowed to stand 24 hours, then filtered and washed, and dissolved in hydrochloric acid. The precipitate was again brought down, a few drops of magnesium chloride being added, filtered off, washed, dried at 100° , and ignited like the molybdenum precipitate. The sulphuric acid was determined in the filtrate after evaporation of the ammonia.

Results obtained are very good. In a note Jannasch remarks that no priority can be claimed for the method, and all that is claimed is the proof that the method is applicable generally to inorganic sulphides (besides organic). The mode of carrying out the analysis is simpler than the method used by Sauer (see this Journal, 1890, 330).—T. L. B.

The Determination of Sulphur in Galena, and in Minerals containing Lead. P. Jannasch and K. Aschoff. J. Prakt. Chem. 1892, **45**, 103—109.

AFTER trial of a number of methods for oxidising the sulphide by means of oxygen, the following was adopted as the only one capable of giving complete oxidation. The galena is very finely powdered and introduced into a porcelain boat, which is then placed in a combustion tube; the whole is then heated, a quick current of oxygen containing oxides of nitrogen (obtained by bubbling the oxygen through fuming nitric acid) being passed the while. Hydrogen peroxide is used in the receivers (see foregoing abstract). For about 20 minutes a dull red heat only is necessary, then a higher temperature is used for an hour. The nitric acid bottle is replaced by a flask containing ammonium carbonate, which is gently warmed, and the current of oxygen is replaced by a current of air. After half an hour's strong heating the chief reaction begins, and is evidenced by fusion of the material in the boat; completion of the reaction takes place in less than an hour from this point. The residue in the boat is now completely oxidised and contains no sulphate, the whole of it having passed as ammonium sulphate to the receivers.

The replacement of oxygen by air during the second part of the operation is rendered necessary owing to the liability to explosions; during the use of the ammonium carbonate it is likewise absolutely necessary to watch all passages, as blocking may occasionally occur.

Comparative analyses show:—

—	Dry Way.	Wet Way.	Theory.
S	13.32	13.50	13.40
Pb	85.99	85.47	86.60
Gangue	0.42	0.42	..
	99.73	99.39	100.00

The method as described is perfectly easily applicable to the analysis of the mineral boumonite; it is to be noted, especially in this latter case, that the temperature must be raised to redness quite gradually, after which heating at a strong red heat for an hour and a half in a current of air and ammonium carbonate takes place as before.—T. L. B.

Wet Methods of Analysis of Galena. P. Jannasch and K. Aschoff. J. Prakt. Chem. 1892, 110—111; and P. Jannasch and T. Bickes, J. Prakt. Chem. 1892, **45**, 111—113.

THE use of chlorine may be conveniently replaced by bromine as follows:—

The powdered mineral is treated in a large crucible with tolerably strong nitric acid, and the sulphur thereby separated is oxidised by bromine. The lead sulphate is dissolved in caustic soda and the whole is largely diluted with hot water, so that the gangue may be filtered off. Now, instead of chlorine being passed into the solution, bromine is added and allowed to act in the cold, heating on the water-bath being resorted to finally for purposes of driving away the bromine.

Another convenient method of analysis is as follows, the lead being precipitated by hydrogen peroxide in ammoniacal solution. Half a gram. of the finely-powdered mineral is oxidised as before in a large porcelain crucible and the whole is then taken to dryness. The residue is evaporated three or four times with concentrated hydrochloric acid, so as to decompose the small quantities of lead bromate formed, and the lead sulphate then got into solution by aid of 10 cc. of ammonia and 10 cc. of glacial acetic acid together with the necessary amount of water. This solution, covered, is warmed on the water-bath and filtered from gangue, the filter being washed thoroughly with a hot dilute solution of ammonium acetate. Lead is precipitated in the filtrate by addition, in the cold, of a mixture of ammonia and hydrogen peroxide; at the end of an hour filtration may be performed, the washing being done with cold water. In order to obtain a good result precipitation must be performed in the well-cooled solution. The sulphur may be determined in the usual way by precipitation with barium chloride, in the filtrate.—T. L. B.

Employment of Cadmium in Gold Bullion Assays. C. Whitehead. Jour. Franklin Inst. 1891, **132**, 365—369.

GREAT difficulties are encountered when it is desired to determine a small percentage of silver in bullion containing platinum or copper or both. Making an alloy containing added silver and lead is unsatisfactory, inasmuch as the comparative insolubility of lead nitrate renders it impossible to extract all the silver-lead alloy from the gold. The author recommends as successful the following modification of Balling's cadmium treatment:—0.5 gram. of the refractory bullion is heated with 10 grms. of potassium cyanide; when the latter is well fused 1 gram. of cadmium is dropped in and the molten mass is poured on a slab to cool. After washing, the alloy, being very brittle, is pulverised and

treated with nitric acid, sp. gr. 1.278, along with 1.004 grm. of silver; the total silver is then determined either as chloride or thiocyanide, neither of which determinations are interfered with by the cadmium nitrate. The result is compared with a proof assay made with 1.004 grm. of pure silver dissolved in the same amount of acid.—D. A. L.

Quantitative Analysis by Electrolysis. F. Rüdorff.
Zeits. f. angew. Chem. 1892, 3—7.

In reference to this branch of analytical chemistry, the author remarks, that proposed methods for the estimation of particular metals by means of electrolysis are not only very numerous but to some extent contradictory, so that it is difficult for chemists to make a selection. The author has therefore submitted all the proposed methods to comparative practical tests, in order to ascertain which are the most suitable for use in an ordinary laboratory where costly and exceptional apparatus are not readily accessible. The requirements, in his opinion, are:—A cheap source of electricity, which must be always available and simple to handle; and a method as exact and as reliable as the ordinary gravimetric methods now in use. Of all the sources of electricity investigated by the author, including dynamos, accumulators, Daniell's cells, Bunsen's elements, &c., the Meidinger elements are accepted as the most generally suitable for the purpose under consideration. These elements are neither dear to purchase nor to keep in order, and when properly charged their activity remains for months almost unaltered. The strength of current obtainable from them, as indicated by cc. of water-gas per minute in a voltameter is as follows:—

	Cc.
8 elements.....	2.6
6 "	1.9
4 "	1.2
3 "	0.8
2 " about.....	0.02

The apparatus employed by the author consists of a platinum dish 60 mm. high, 75 mm. diameter at the top, about 40 grms. weight and 170 cc. capacity, and a piece of thick platinum wire bent into a helical form at one end. The condition of the precipitated metal is greatly influenced by:—1. The intensity of the current; 2. The concentration of the solution; and, 3. The substances added to the solution undergoing electrolysis. It is in this latter point that most of the proposed methods vary. In the estimation of copper, for instance, by the Luckow method, so much nitric acid is added that the precipitated metal has to be washed while the circuit is still closed, which is undesirable; and Classen's suggestion of adding an excess of ammonium oxalate does not improve matters. The following is a successful method:—A solution containing 0.1 to 0.4 of copper as nitrate or sulphate, after any free acid has been neutralised with ammonia or soda, is mixed with 5 drops of nitric acid, sp. gr. 1.20, diluted to about 100 cc. and electrolysed with 2 to 6 Meidinger elements over night. When the electrolysis is complete, about 10 drops of a saturated solution of sodium acetate are added, the circuit is then broken and the bright pale red precipitate of copper adhering firmly to the dish is well washed, drained, dried at 100° and weighed.

The presence of chlorides would cause the metal to form a spongy deposit, but this is prevented by adding 2 to 3 grms. of ammonium nitrate, 20 cc. of ammonia, sp. gr. 0.91, and water to make volume up to 100 cc., then electrolysing with 4 to 6 Meidinger cells, and when precipitation is complete, saturating any free ammonia with acetic acid, before opening the current. In the presence of iron, 2 or 3 drops of concentrated sulphuric acid are added instead of the nitric acid, the precipitated copper has not then such a good appearance, but the estimation is nevertheless trustworthy. Mercury is readily estimated in a solution containing 0.1 to 0.3 grms., any free acid being first neutralised by alkali, to which any of the following additions are made:—5 drops of nitric acid, sp. gr. 1.20; 5 drops of dilute (1:10) sulphuric acid; 1.5 grm. of tartaric acid, and 10 cc. of ammonia, sp. gr. 0.91; 5 cc. of nitric acid;

10 cc. of a saturated solution of sodium pyrophosphate, and 13 cc. of ammonia, or about 1 grm. of potassium cyanide, making up to 100 cc. with water, and electrolysing over night with 2 to 6 cells. Then adding 10 cc. of the saturated solution of sodium acetate, disconnecting, and washing the bright mirror or adhesive lustrous globules of deposited mercury first with water, then with alcohol, allowing to drain and ultimately to dry over sulphuric acid. For the electrolytic estimation of silver, the addition of ammonium sulphate and ammonia has not proved satisfactory in the hands of the author, but excellent results are obtained by using a solution containing 0.1 to 0.3 grm. of silver, neutralising any free acid with soda, adding slight excess of potassium cyanide, making up to 100 cc., and electrolysing over night with 3 to 6 Meidinger cells. The dull white adhesive precipitate of silver is washed with water and dried at 100°. The best process for estimating nickel, in the absence of chlorine, is by adding 25 cc. of a saturated solution of ammonium sulphate and 25 cc. of ammonia, sp. gr. 0.91, to a solution containing from 0.1 to 0.3 grm., diluting to 100 cc., and electrolysing with 3 to 6 elements over night. The moderately bright, platinum like, adhesive deposit of nickel is washed with water, dried at 100°, and weighed. With 20 cc. of a saturated solution of sodium pyrophosphate instead of the ammonium sulphate the nickel separates out dull and grey. Cobalt is estimated in the same way as nickel, using six to eight cells; the deposit is dull and grey. In the case of cadmium various additions give unsatisfactory results, and as sodium acetate and acetic acid, or oxalates, in ammonia, or sodium pyrophosphates and ammonia, the following treatment is, however, efficient: The neutral solution, containing from 0.1 to 0.4 of the metal is mixed, until clear, with potassium cyanide, made up to 100 cc., and electrolysed with three to six cells over night. The dull grey adhesive precipitate of cadmium is washed first with water, then with alcohol, and dried at 70°—80°. Of the numerous suggestions for estimating manganese, the author selects the following:—The manganese must be present only as sulphate, and must not exceed 0.04 grm. in quantity. To such a solution three drops of dilute (1:10) sulphuric acid are added, and the volume is made up to 100 cc.; two cells only are used for the electrolysis, or six cells may be divided between three dishes working simultaneously, and the dish is connected with the positive electrode and not the negative as in all the cases hitherto considered. The precipitate is washed with water, drained, dried over sulphuric acid, and then at 60°, inasmuch as at this temperature the composition remains constant as $MnO_2 + H_2O$, and the author considers this mode of procedure more trustworthy than ignition to Mn_2O_3 ; the numbers obtained multiplied into 0.523 give the proportion of manganese in the precipitate. The dry precipitate is brown with metallic lustre and adheres well to the dish. The dish in this instance is best cleaned by dissolving the precipitate in very dilute sulphuric acid, to which some hydrogen peroxide is added; in the other instances the same object is effected by the use of dilute nitric acid. Further communications on the fifth subject are forthcoming.—D. A. L.

Estimation of Aluminium in Ferro-Aluminium. E. Donath.
Zeits. f. angew. Chem. 1892, 13.

The author, referring to F. Regelsberger's paper on the estimation of aluminium in its alloys (this Journal, 1891, 1033), points out that he investigated the cyanide method in 1880, and found that the presence of much iron was unfavourable. Therefore, when small quantities of aluminium are to be determined in the presence of large quantities of iron, it is considered preferable to precipitate all the aluminium with a little of the iron, and proceed with the estimation in this precipitate. Moreover, for the reduction, the author prefers using sodium sulphate to either sodium hydrogen sulphite or ammonium cyanide suggested by Regelsberger; working with boiling ammonium cyanide is any way not agreeable.—D. A. L.

A Quick and Reliable Method for the Decomposition and Analysis of Ferrochrome. H. N. Warren. Chem. News, 65, 186.

The finely powdered substance is treated in a flask with strong sulphuric acid and gently heated, SO_2 is evolved, and the heat is raised until the sulphuric acid begins to volatilise. In this way the ferrochrome is completely dissolved in a few minutes. A few drops of hydrochloric acid are added, the solution is diluted, filtered, and made up to a known volume. An aliquot portion is titrated with standard bichromate for iron; and the chromic and ferric hydrates precipitated in another portion, from these the percentages of iron and chromium may be obtained.

—J. C. C.

Formation and Behaviour of Basic Calcium Phosphates and their Relationship to Thomas-slag. O. Foester. Zeits. f. angew. Chem, 1892, 13—22.

The proneness of calcium and phosphoric acid to form basic salts has long been realised. Thus it is known that tricalcium phosphate is decomposed and yields up some of its phosphoric acid to hot solutions of sodium or potassium carbonate, or when ignited with these salts; and, moreover, when the hydroxides of these metals are used in moderately strong solution, a residue remains containing calcium oxide and phosphoric acid in the proportions of 10 mols.:3 mols., and to which the formula $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ has been ascribed. The same compound is obtained whether mono-, di-, tri-, or pyrocalcium phosphate is employed. With very strong alkali and prolonged boiling the proportion of phosphoric acid remaining in the residue can be reduced to 1 mol.:4 mols. of lime. The compound $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$, prepared by igniting di- or tricalcium phosphate with calcium dihydroxide or carbonate, although not attacked by dilute alkali, can be brought to yield a residue of 1 CaO :1 P_2O_5 with very strong alkali. Whilst basic cinder and tetra-calcium phosphate, obtained by strongly igniting di- or tricalcium phosphate with the requisite proportion of lime, yields up their phosphoric acid more readily still, and leaves a residue in which the proportion of phosphoric acid to lime is 1 mol.:5 mols. Sugar solution does not extract lime from the products, $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{Ca}(\text{HO})_2$, of the decomposition of di- or tricalcium phosphates, thus showing that all the lime in this compound is in combination, but as long as any water is retained by it it is soluble in citric acid. On the other hand, by drying at a high temperature it becomes almost insoluble, owing to the formation of the anhydrous compound. This is the compound which is found in ordinary blowpipe ignitions, but at the temperature of the softening of wrought iron tetra-calcium phosphate is formed, for even if the quantity of lime present is insufficient to convert the whole of the phosphoric acid into tetra-compound, a mixture of it with tricalcium phosphate and $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ is obtained. The products of the decomposition of calcium phosphates containing a large proportion of lime appear by their behaviour not to be chemical compounds, but mixtures of $\text{Ca}_3\text{P}_2\text{O}_8$, $\text{Ca}(\text{OH})_2$ with free $\text{Ca}(\text{HO})_2$.

The phosphoric acid can be abstracted from calcium phosphates far more readily and more completely by fusion with alkalis; in fact, by repeated and continued fusion the whole of their phosphoric acid can gradually be extracted, especially when there is free access of carbonic anhydride. All calcium phosphates give by fusion with alkalis a mobile, transparent, and molten mass, which becomes opaque when solid, and by treatment with water leaves a residue containing all the lime mostly as carbonate, but some free, and the remainder not as $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$, but as tricalcium phosphate. It is assumed that really all the calcium phosphate undergoes decomposition, but that during the treatment of the fused mass with water a partial re-combination takes place resulting in the formation of some tricalcium phosphate.

In order to ascertain the composition of the various products of these and subsequent experiments, the products are: 1. Ignited with ammonium carbonate; 2. Suspended in water and exposed for some time to a current of carbonic anhydride to remove any carbonate of lime; 3. The lime

soluble in a solution of sugar is estimated and extracted; 4. The products are treated with dilute acetic acid in quantity insufficient for solution; 5. They are also digested at 40° — 60° for 10 hours with 100 parts of 5 per cent. citric acid solution. In both the latter cases the composition of the insoluble residue is ascertained, and in almost all cases the residue from the citric acid treatment is $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$. The author has made numerous experiments on the action of these various solvents on the different calcium phosphates, examining in all cases intermediate products; with carbonic anhydride and water, for instance, tricalcium phosphate is partially decomposed into dicalcium phosphate and calcium carbonate, whereas $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ is converted into $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaCO}_3$ and tetra-calcium phosphate remains unaltered. By dilute acetic acid tricalcium phosphate is very slowly half changed into dicalcium phosphate, whilst $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ after some time only gives up its extra molecule of calcium oxide, but tetra-calcium phosphate is quickly and completely converted into dicalcium phosphate by this reagent. By treatment with a 5 per cent. solution of citric acid, which also gives a measure of the solubility, of the phosphoric acid in the soil, in proportions of 100 cc. to one gm. of phosphate, and at 40° to 60° for about 10 hours, both unignited tricalcium phosphate and tetra-calcium phosphate pass completely into solution; ignited tricalcium phosphate leaves a residue which contains somewhat more lime than the preparation employed, but $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ undergoes no change.

Similar products to those obtained with the alkaline lye are produced by heating dried mixtures of aqueous phosphoric acid, mono-, di-, or tricalcium phosphate with the proportion of lime, quick or slacked, or calcium carbonate, required to form the basic salt. In these cases the extent of the decomposing action on the tricalcium phosphate, first formed or already present, depends on the degree of heat and the duration of the heating. The mixtures were therefore ignited:—1. Many days in a potter's kiln. 2. Many hours in a good drawing reverberating furnace, fired with wood, charcoal, and coke. 3. Two hours at a temperature sufficiently high to render wrought iron plastic without melting it. The first two temperatures occasioned considerable shrinkage of the mixtures and yielded a caked, but not sintered, friable product; whilst the product of the third and highest temperature employed was a strongly sintered partially fused mass, with a distinctly stallate, crystalline structure, but of slight hardness.

With regard to the chemical behaviour of these mixtures under these conditions, a noteworthy formation of tetra-calcium phosphate only regularly occurred at the highest temperature used, although it was observed occasionally in the reverberatory product; but, in fact, at the lower temperatures the greater part of the tricalcium phosphate combined with the excess of lime to form $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$. The products in which the saturation of the phosphoric acid had only arrived at this stage, yielded only traces of phosphoric acid to boiling alkalis, but when heated with ammonium carbonate, no matter what the proportion of lime to phosphoric acid had been employed in the original mixture, they absorbed so much carbonic anhydride that after the removal of the calcium carbonate, $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ alone remained. Under the simultaneous action of water and carbonic anhydride things were different, for then so much carbonic anhydride is absorbed that, after the removal of the calcium carbonate, tricalcium phosphate remains. Perhaps, in this instance, the apatite-like compound, $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaCO}_3$, is formed, which is the preponderating mineral constituent of limes.

The products of the higher temperature behave quite differently, for, although in no case consisting entirely of tetra-calcium phosphate, owing probably to the fact that the mixtures never fused, yet in all these experiments evidence of its presence in large quantities is obtained; they yield plenty of phosphoric acid to boiling alkali, also to citric acid, and are readily and completely changed to dicalcium phosphate by dilute acetic acid, &c.; in fact, the citrate insoluble portion consists of $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$. Moreover, they are not acted on by prolonged exposure to water and carbonic anhydride, and they do not contain any lime soluble in sugar solution.

The author reviews, criticises, and discusses the various opinions which have been advanced for and against the existence of the tetra-basic calcium phosphate in basic cinder, the ultimate conclusion being that not alone does it exist, but that all the phosphoric acid in basic cinder ought to be there as tetracalcium phosphate, in fact, under the conditions of its formation, could not be present in any other state of combination. Nevertheless, chemical examination of different samples of basic cinder always indicates the presence of a certain irregular amount of phosphate, which is not soluble in citric acid or ammonium citrate, and which, therefore, cannot be tetracalcium phosphate. This has hitherto been very generally, but in some cases erroneously, attributed to admixture with some adulterant. The author has, however, investigated the point, and finds that when tetracalcium phosphate is exposed to a temperature somewhat below its temperature of formation that it undergoes reversion with the setting free of lime and the formation of $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ or in the presence of much silica, $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaSiO}_3$. The free lime has been extracted by means of sugar solution, and found to be present in the proper proportions required by—

This change takes place more readily in the presence of air. The author is, therefore, of opinion that the presence of citrate insoluble calcium phosphate in basic cinder is to be ascribed to the treatment the cinder undergoes after leaving the converter, and that, in fact, it is the result of the re-conversion of some of the tetracalcium phosphate, in the manner just set forth, during the slow cooling of the mass of heated cinder in the air; the comparatively small proportion of insoluble phosphate found in slag may be accounted for by the reasonable assumption that in such a complex environment the free lime, as well as the phosphates, would probably enter into some other state of combination; and this assumption has been to some extent experimentally confirmed. Moreover, $(\text{Ca}_3\text{P}_2\text{O}_8)_3\text{CaO}$ is not absolutely insoluble in citrate, and therefore in the fine state of division in which it exists in basic cinder, it may probably pass into solution in larger quantities than might be anticipated. The presence of citrate in soluble calcium phosphate may also, perhaps, in part be ascribed to lime being present in insufficient quantity to change all the phosphoric acid into the tetracalcium salt. It seems, however, worth while trying if more rapid evolving of basic cinder will prevent the formation of the inferior calcium phosphate.

Taking into consideration the much greater facility with which tetra-basic phosphate undergoes decomposition in the soil, and conversion into di-calcium phosphate, as compared with tri-calcium phosphate, the author suggested that the two of the lime molecules must be in looser state of combination. The following formulæ are furnished to give a graphic representation of such an arrangement:—

Tri-calcium phosphate—

Tetracalcium phosphate—

The Separation of Arsenic, Antimony, and Tin. John Clark. Proc. Chem. Soc. 1892 [110], 68—70.

The mixed sulphides of arsenic, antimony, and tin obtained in the ordinary course of analysis are dissolved in a strong solution of ferric chloride in chlorhydric acid, and the arsenic is distilled off and weighed as trisulphide. The residual liquid contains the antimony as trichloride, and the tin as stannic chloride, also ferrous and ferric chlorides. The author corroborates Loveton's statement that antimony and tin can be separated by taking advantage of the difference in solubility of their sulphides in solutions of hydrogen chloride of certain strengths, but thinks the proportion of acid should be reduced from a half to a third, to ensure the complete precipitation of the antimony, and to avoid the necessity of filtering through cotton wool. He recommends a combination of Loveton's and W. F. Clarke's processes, and without removing the iron salts he precipitates the antimony with hydrogen sulphide in a tepid solution containing from one-third to one quarter of its volume of chlorhydric acid and a considerable quantity of oxalic acid. The precipitate, which is free from tin, is washed first with water, then with alcohol, and finally with carbon bisulphide, and weighed as Sb_2S_3 after being heated at a temperature of about 130° to ensure the complete expulsion of water. He considers this temperature sufficiently high to dry the Sb_2S_3 . He points out that when Sb_2S_3 is dried at 130° , it suffers little or no further loss in weight till it is raised to the temperature at which it is converted into the black sulphide, and his experiments indicate that the loss in weight observed at this stage is not due to water, but to oxidation, as after heating between 200° and 230° for several days there was a continuous loss, the black sulphide becoming brown, and it was found by analysis to consist chiefly of oxide of antimony.

When the Sb_2S_3 precipitate is large it is necessary, after drying, to digest it in carbon bisulphide to extract the whole of the sulphur. To obviate this objection the author reduces the excess of ferric chloride with thin sheet iron, and as soon as the yellow colour has disappeared the undissolved iron is removed and the antimony which has come down is redissolved with the aid of a little ferric chloride, which is added drop by drop till the solution is distinctly yellow to ensure that all the tin is in the stannic state; a warm solution of oxalic acid containing about one-third of its volume of chlorhydric acid is then added, and the antimony is precipitated as Sb_2S_3 , together with traces of sulphur, and washed with water, alcohol, and carbon bisulphide.

After the removal of the antimony the hydrogen sulphide is expelled by boiling, the oxalic acid decomposed with potassium permanganate, and the tin precipitated in a hot solution with hydrogen sulphide, and allowed to stand till cold. The SnS_2 obtained in this way can be filtered off and washed with water without passing through the filter. It is then converted by ignition into SnO_2 , in which form the tin is weighed. The test analyses are very satisfactory.

For qualitative purposes in distilling off the arsenic a condenser is not necessary, a bent tube dipping into water being sufficient. It is advisable, however, to use a safety-tube to prevent the distillate coming back.

In the case of alloys the metal is dissolved in strong chlorhydric acid with the aid of ferric chloride, and the arsenic distilled off at once. The antimony and tin after being separated from the other metals of the group are then estimated in the manner described above.

ORGANIC CHEMISTRY.—QUALITATIVE.

A Colour Reaction of Acid Anilides. J. Tafel. Ber. 1892, 25, 412—413.

MANY acid anilides give with concentrated sulphuric acid and potassium bichromate, or lead peroxide, colourations similar to those obtained with alkaloids under like conditions: unlike acid hydrazides, phenylhydrazones, and phenylselenozones, the acid anilides give no colouration with sulphuric acid and ferric chloride.

The reaction is best carried out by dissolving a few milligrammes of the anilide in sulphuric acid and then adding a little powdered potassium bichromate; under these conditions the anilide and the hydrazide of one and the same acid give the same colouration. The reaction is given by all simple anilides and by all phenylcarbamides, but not by the products of the interaction of acetic anhydride and benzoic chloride with ethyl- and methyl-aniline.

Acetylparatoluidine gives no colouration but acetylorthotoluidine does; the acetyl and benzoyl derivatives of α - and β -naphthylamine give a dirty brown colouration.

The following compounds give the reaction:—Acetanilide, reddish-violet; propanilide, blood red; ethyl oxanilate, magenta red; oxanilide, violet; oxalacetanilide, magenta-red; benzanilide, violet; symmetrical diphenylcarbamide, bluish-violet; symmetrical ethylphenylcarbamide, rose-red; asymmetrical ethylphenylcarbamide, cherry-red; acetylhydrazobenzene, blood-red; acetylorthotoluidine, cherry-red; dibenzoylmecaphenylenediamine, blood-red; benzoyltetrahydroquinoline, blood-red; acetyltetrahydroquinoline, rose-red.—F. S. K.

The Technical Analysis of the Calcined Vinasse from Beetroot Molasses. C. Heyer. Chem. Zeit. 1891, **15**, 1489—1490, 1523—1524, and 1557. (Compare this Journal, 1891, 861.)

The author gives the following scheme for the analysis of this substance. The sample is pulverised, mixed and stored in a dry bottle fitted with a caoutchouc stopper. (1.) *Moisture*:—5.12 grms. are heated in a drying oven at 110° until of constant weight. (2.) *Insoluble matter*:—20 grms. are slowly added to 250 cc. of boiling water contained in a beaker, boiled, and after well stirring and allowing to remain for 15 minutes, collected on a tared filter previously dried at 110° C., washed with boiling water and finally dried at 110° C. until of constant weight; the filtrate and washings are made up to 500 cc (see below). After ascertaining the weight of the insoluble matter dried at 110° C., it is ignited, and the amount of fixed matter determined by reweighing this. (3.) *Alkali salts*:—Four 25 cc. portions of the filtrate and washings mentioned above (each corresponding to 1 gm. of vinasse) are evaporated to dryness in tared dishes on the water-bath, the residue carefully calcined, ignited, and weighed; the numbers deviate from one another at most 0.1 per cent. (4.) *Potassium chloride*:—One of the last-mentioned residues is dissolved in water exactly neutralised with nitric acid, boiled to remove hydrocyanic acid when present, and titrated with $\frac{N}{10}$ silver solution, employing potassium chromate as indicator. (5.) *Potassium sulphate*:—Another of the residues is dissolved in 100 cc. of water, an excess of hydrochloric acid added, and after boiling the solution with a small quantity of nitric acid or bromine water, it is precipitated with a boiling solution of barium chloride, the barium sulphate being collected as usual and weighed; it is calculated to K_2SO_4 . (6.) *Potassium phosphate*:—To 250 cc. of the standard solution an excess of nitric acid and ammonium nitrate (40 grms.) are added, it is then precipitated with molybdenum solution, and finally converted in the usual manner into magnesium pyrophosphate, weighed as such and calculated to $K_4P_2O_7$. (7.) *Potassium carbonate*:—A portion of the ignited residue from 25 cc. of the solution is dissolved in water in a 100 cc. flask, boiled with an excess of hydrochloric acid, and exactly precipitated with the quantity of barium chloride calculated

from (5); then cooled, made up to the mark, and filtered through a dry filter. 20 cc. of the filtrate are evaporated on the water-bath with platinum chloride solution (10 cc., containing 1 gm. P₂O₅), 80 per cent. alcohol poured over the residue, and allowed to remain for half an hour; then washed by decantation with 80 per cent. alcohol, brought on to a tared filter previously dried at 120°, and finally, after drying at the same temperature, weighed. This is calculated to K_2CO_3 and represents the total potassium, the amount of potassium carbonate in the sample being arrived at by deducting from it that of the other potassium salts as found, likewise calculated to K_2CO_3 . It is unnecessary to correct for the volume of the barium sulphate precipitate, as the slight raising of the results occasioned thereby is compensated by the lowering of the same due to the co-precipitation of a small quantity of potassium chloride with the barium sulphate. (8.) *Sodium carbonate*:—This is obtained by deducting the sum of the percentages of K_2CO_3 , KCl, K_2SO_4 , and K_3PO_4 found from that of the total alkali salts (3), and may be controlled by determining the alkalinity, calculating this to K_2CO_3 , deducting the K_2CO_3 found from it, and calculating the difference to Na_2CO_3 . (9.) *Alkalinity*:—This is determined by dissolving the residue from 25 cc. of the standard solution in water and titrating with normal sulphuric acid; or 25 cc. of the solution may be directly titrated with normal nitric acid, and this used for the chlorine estimation (4). The following analysis of a sample of the calcined vinasse by the above scheme is given:—

	Per Cent.
K_2CO_3	59.03
KCl.....	15.18
K_2SO_4	4.26
K_3PO_4	0.29
Na_2CO_3 (from alkalinity 15.06 per cent.).....	15.14
Insoluble matter (organic, 1.15 per cent.; inorganic, 3.95 per cent.).....	5.10
Moisture.....	0.87
Total.....	99.87

The ordinary way of determining the amount of potassium and sodium, viz., precipitating the solution acidified with hydrochloric acid with an excess of barium chloride, rendering alkaline with ammonium carbonate, filtering, washing with ammoniacal water, evaporating, igniting, extracting with water and filtering from silica, then again evaporating, igniting, weighing the soluble chlorides, and finally separating them with platinum chloride gives good results, but the author contends that the same accuracy is attainable by the method given above (7 and 8), which is much more expeditious. The strength of the alcohol employed to wash the platinochlorides (80 per cent.) is that recommended by Fresenius, and the author makes use of the factor (0.2832) adopted by this chemist for calculating potassium platinum-chloride to the carbonate. (Compare following abstract).—A. R. L.

The Technical Analysis of the Calcined Vinasse from Beetroot Molasses. Alberti and Hempel. Chem. Zeit. 1891, **15**, 1623—1624.

The authors point out that Heyer (preceding abstract) has not taken into account the estimation of silica, and they disagree with him in calculating the total sulphur as potassium sulphate. They propose the following alterations in (5) and (7) *loc. cit.*:—The ignited residue from a 25 cc. portion of the solution is acidified with an excess of hydrochloric acid, evaporating to dryness, and heated at 105°—110° for 1—2 hours; it is now extracted with water containing a few drops of hydrochloric acid and filtered from silica, the filtrate being made up to 250 cc. The sulphuric acid is determined in 50 cc. of this; whilst 100 cc. are introduced into a 200 cc. flask exactly precipitated with barium chloride, made up to the mark, and the potassium determined in 25 cc. of the filtrate by the platinum method. The authors further propose to determine the amount of sulphuric acid before and after ignition and in the vinasse, and to calculate the difference as potassium sulphide.—A. R. L.

A Method of Inversion and Estimation of Raffinose.
Kaydl. Oesterr. Zeits. Zuckerind. 1891, 20, 700.

THE method is that of Herzfeld (Deutsch. Zuckerind. 1890, 15, 466), but instead of dissolving the semi-normal weight of sugar in 100 cc. of water, that weight of sugar is dissolved in 250 cc. of water in order that 75 cc. of the solution contains exactly the semi-normal weight in grms. of dry substance. It is applicable to all kinds of products. Herzfeld's constant (~ 32.66) has been fully confirmed. It will be seen that with products of different sugar percentage, but giving the same quotient

of purity, the same quantity of sugar will be inverted, and the influence of the quotients of purity have therefore to be determined. As all experiments show that the (optically inactive?) organic matters (*Nichtzucker*) are without influence, and as all salts raise the constants about the same amount, the amounts of organic matters (*Nichtzucker*) have been neglected, and the inversion-constants determined for pure sugar in the presence of various weights of a mixture of sodium chloride, potassium nitrate, and anhydrous sodium acetate.

The following table was constructed from the results obtained:—

INVERSION-CONSTANTS AT 20° C. FOR THE QUOTIENTS.

Quotients.	95	90	85	80	75	70	65	60	55	50	45	40

25	0.62	0.51	0.51	0.51	0.61	0.71

The author has directly determined the influence of the organic matters (*Nichtzucker*), and found it to be nil. By precipitating the total sugar and raffinose from a technical product by strontia and lime, he obtained a solution polarising slightly to the right, the optical activity not undergoing any alteration when treated with acids. Lead chloride was used as clarifying agent in these experiments, and subsequently three grms. of extracted bone charcoel was added (when necessary); three grms. of this charcoel occupy 1.95 cc., and flasks having two marks (100 cc. and 101.95 cc.) were used. In the analysis of molasses it is preferable to employ Herzfeld's method (semi-normal weight—100 cc.).

The dextro-rotation in the above solution of the organic matters (*Nichtzucker*) and in some other technical products was found to be due to dextrin. The author states that syrups have been obtained by the diffusion process having a purity quotient of 112, which contained as good as no raffinose, but large quantities of dextrin. It is therefore a matter of importance not to make use of the raffinose formula

unless the presence of raffinose is known, in all other cases to calculate the results by Clerget's formula.

A portion of the raffinose present in raw beet sugar is contained in the crystals themselves, and the amount thus occurring is in some cases considerable; it appears to be less dependent on the form of the crystal than upon the quantity of raffinose contained in the solution from which the sugar was crystallised.

To prepare raffinose, a solution of molasses is precipitated with basic lead acetate, filtered and the filtrate reprecipitated with ammonia, again filtered and this filtrate concentrated to a syrup. It is dissolved in strong methyl alcohol, and saturated with carbonic anhydride, and the filtrate from this after distilling off the methyl alcohol, is evaporated to a syrup, a crystal of pure raffinose added, and left in a cool place for 7—8 days.—A. R. L.

On the Quantitative Determination of Mechanical Wood Pulp in Paper. J. Baudisch. *Papier Zeit.* 1891, 16, 2414—2415.

THE method of Godeffroy and Coulon and its importance for the above purpose has already been discussed in this Journal. (See this Journal, 1888, 863—864; 1889, 574—576; 1891, 576—577.) As this test, with the exception of Bamberger's method, is the only one which if properly made gives reliable results, and as Godeffroy and Coulon have only published their preliminary results, the author describes the operation of the method in full. As shown in the notices already referred to, the method is based on the fact, that the incrusting substances of the mechanical wood-pulp reduce certain metal salts, e.g., gold chloride, and that from the quantities reduced we may ascertain the quantities of mechanical wood-pulp that are present in the paper. But also pure wood and straw cellulose, have to a certain extent the same reducing properties, and therefore it is necessary to nullify their influence by a preliminary extraction. The reduction is unaffected by different concentrations of the gold chloride, as long as only weak solutions are employed, and also uninfluenced by the time during which the mechanical wood-pulp is treated by the reagent. From the previously published results (see this Journal, 1889, 576), it is evident that on an average 100 parts of mechanical wood-pulp reduce about 14 parts of gold chloride. This property of mechanical wood-pulp seems to be uninfluenced by the various compositions of different papers, and therefore the same reduction number may be used for all sorts of paper. But the sizing, especially vegetable sizing, does affect this property of mechanical wood-pulp, and it must therefore first be removed. Papers to be tested by this method should first be examined by one of the qualitative reagents for the presence of mechanical wood-pulp, preferably by phloroglucinol and hydrochloric acid. Then three strips, about 2.5 or 3 cm. broad, must be cut from a sheet of the paper in question, in a diagonal direction. One of them is used for the determination of moisture, and then reduced to ash for finding the quantity of mineral substances in the dry paper. The second is used for finding the quantity of ash after the aforesaid extraction has been made; and the third serves for the determination of mechanical wood-pulp. The second and third strips must be freed from animal and vegetable sizing, before the examination is made. To effect this, they are rolled together, placed on glass funnels as filter-papers are, and there washed first with cold, and subsequently with hot distilled water. The presence of animal size is ascertained by the usual test with oxide of mercury. After all animal size has been removed in this way, the resinous sizing substances are extracted with pure absolute alcohol, to which a little tartaric acid is added. Hydrochloric acid must not be used, because of its influence on the fibres as well as on the gold chloride. This mixture of alcohol and tartaric acid must be used hot, and the paper treated with it, until every trace of resinous substance is removed. Finally, traces of tartaric acid are removed by washing with hot water, until the paper ceases to show an acid reaction. The paper strips thus freed from animal and vegetable size, must now be dried absolutely at a temperature of 100 to 110 C., and then weighed. One of them is then treated with pure absolute alcohol, and subsequently with pure ethyl-ether for 24 hours each, in order to remove straw and wood cellulose if present. The residue is dried and weighed again, and afterwards reduced to ash which is weighed. The third strip, after having been absolutely dried and weighed, is torn into small pieces, which are put into a beaker, and some diluted gold chloride solution added, which, however, should not be too weak. It is then boiled for 10 or 15 minutes, allowed to cool, filtered and washed with distilled water. The filter and its contents are then absolutely dried at 100 to 110 C., and both reduced to ash and the latter weighed. The weight of the filter ash is now known, the weight of the ash of the paper strip is likewise known, and therefore the weight of the reduced gold is found by subtraction, and by means of the above proportion the quantity of mechanical wood-pulp contained in the paper is discovered.—H. S.

Determination of Mechanical Wood-pulp in Paper. R. Godeffroy. *Mitt. k. k. techn. Gew. Museum*, 1891, 295.

THE reducing action of the lignocelluloses upon gold chloride has been shown by Godeffroy and Coulon (*ibid.* 1888, 18, 62; 1889, 9; this Journal) to be available as the basis of a quantitative method of estimation of mechanical wood-pulp in paper. Pulp from the fir, willow, elm, acacia and pine, were found to be approximately equal in reducing power, the quantity of gold reduced in the boiling solution of the chloride being 14 per cent. of the weight of the lignocellulose. In applying the method to papers, it is necessary to eliminate sizing constituents before applying the tests. With the view of simplifying the process of purification previously given (*loc. cit.*) the author has investigated a number of treatments, of which the most satisfactory is to boil with 10 per cent. aqueous ammonia. By this treatment, the reducing power of the lignocelluloses investigated, viz., pine, fir, poplar, maple and hazel, was found to be increased by exactly 50 per cent.

The simplified method consists in the following operations:—

(a) boiling in 10 per cent. aqueous ammonia for 10 minutes, followed by an exhaustive wash. Two portions of the paper are treated simultaneously. They are then dried, one is reduced to ash, and the quantity of the latter estimated; the other is subjected to (b) boiling for ten minutes with the solution of gold chloride, washing, drying, and burning. From the weight of ash obtained, that in the untreated paper is deducted giving the weight of gold which, multiplied by 100 and divided by 21.2, gives the percentage of lignocellulose in the paper.

Investigations with the view to substitute for the gold salt, less expensive reagents, viz. alkaline solutions of copper and bismuth oxides, were attended with negative results, the reduction numbers obtained with these reagents being variable.—C. F. C.

Analysis of Sealing Wax. C. Mangold. *Zeits. f. angew. Chem.* 1892, 75—76.

AN attempt was made to ascertain the composition of sealing wax by aid of the iodine equivalent of its alcoholic solution. Boiling alcohol dissolved 66 per cent., the remaining 34 per cent. being taken as the total mineral matter. From the iodine equivalent it is calculated that the 66 per cent. of soluble matter consists of colophonium (formed by heating the shellac and turpentine together), and shellac in the relation of 36 to 30.—T. L. B.

On the Estimation of the Organic Substances in the Air by Potassium Permanganate. J. Areharow. *Arch. Hyg.* 1891, 13, 229.

THE author's experiments prove that the difference in the amount of organic matter in the air of different dwelling rooms can be estimated by potassium permanganate, when this difference amounts at least to 25 per cent. He employs a specially constructed apparatus by which the air is in complete contact with the permanganate solution.

The following precautions are necessary:—(1.) The air must pass through the solution which is heated to a fixed temperature (43 C.) in very small bubbles. (2.) In order that the end reaction shall be sharp, the solution must be strongly acidified. (3.) All the glass or porcelain apparatus employed in the determination must previously be boiled with permanganate solution. (4.) The whole process must always be conducted in the same manner in order that the unavoidable errors may be kept constant. (5.) Strong solutions are not so accurate as dilute ones. The best concentration is 0.026 mgrms. of potassium permanganate to a litre of water.—A. R. L.

On the Estimation of Fatty Matters in Milk-products.
Lézé and Allard. *Compt. Rend.* 1891, **113**, 654—656.

LÉZÉ described in 1890 (*Compt. Rend.* **110**, 647; see this Journal, 1890, 660) a method for estimating fatty matter in milk, which consisted in adding 4—5 vols. of pure concentrated hydrochloric acid (enough to redissolve the casein precipitated at first) saturating with ammonia, and diluting till all the fatty matter was raised into the neck of the flask in which the operations were executed, which was graduated into tenths of a cc. The flask was then heated for some hours to 40° in an oven. The authors have improved the method and generalised it. The separation of fatty matter from casein solution takes place more satisfactorily if the flask be left at the ordinary temperature, or better at 25°—30°. It is, however, to be heated finally to 40° on the water-bath, this temperature being necessary to unite the drops of fatty matter. The neutralisation with ammonia is unnecessary. The hydrochloric acid used must be absolutely free from chlorine, as otherwise a flocculent precipitate is produced and gas is given off which renders it difficult to read off the volume of butter. The fatty matter is pure milk butter.

By this action of hydrochloric acid, it is easy to isolate completely, and estimate easily, the fatty matter of milk, cream, cheese, &c., and also of margarine. When the substance is too pasty to be introduced at once into the flask with the graduated neck, it is first treated in an evaporating dish, and then transferred to the flask. In all cases it is treated with hydrochloric acid until it is dissolved to a liquid, which becomes brown in colour on warming, but remains limpid, while the fatty matter separates out. Many bodies have been examined and an estimation of fat in a sample of Gruyère cheese is quoted.

	Per Cent.
Water.....	28.20
Fatty matter extracted with ether.....	31.84
" " carbon disulphide .	32.04
" " by the new method	31.75

In this case the operation was carried out by treating 10 grms. of cheese with 50 cc. of pure hydrochloric acid, leaving it to digest for a quarter or half an hour, and then warming on the water-bath till the liquid turned brown. Lukewarm water was then added till the fat could be read off on the divided scale on the neck of the flask. The density of butter at 40° is 0.90, so that to obtain the weight, the volume must be multiplied by this number; if 9 grms. of the substance be taken the volume read off in tenths of a cc. gives directly the percentage of butter in the products.

—P. J. H.

ANALYTICAL AND SCIENTIFIC NOTES.

On the Existence of Acid and Basic Salts in very dilute Solutions. D. Berthelot. *Compt. Rend.* 1891, **113**, 641—643.

This is a study of the constitution of dilute solutions by means of their electric conductivity. Gradually increasing quantities of a solution of a strong acid, such as hydrochloric acid, are added successively to an equivalent solution of a strong base, such as potash, and the variation of the conductivity with the composition is represented graphically by plotting the conductivities of the solutions as abscissæ and the relative proportions of one of the bodies (e.g. the alkali) as ordinates. The figure obtained (whether the acid be added to the alkaline solution, or the reverse), consists of a system of two straight lines whose directions are inclined to each other at an acute angle, and which are joined by a short curved line. The one straight line corresponds to the solutions in which there is an excess of alkali, the other to those in which there is an excess of acid. But the fact that both in acid and alkaline solutions the variation of the conductivity with the composition ceases to be linear in the immediate neighbourhood of the point of neutralisation proves that a small quantity of a second salt (acid or basic, as the case may be), is formed; in many cases these salts are known in the solid state, e.g., the oxychlorides and the hydrochlorides of the chlorides. To avoid

all suspicion that the curved position of the system may be due to the presence of dissolved carbonate, the author has experimented with a solution of baryta (1 litre = $\frac{1}{217}$ gramme-molecule) to which were added gradually increasing quantities of hydrochloric acid (1 litre = $\frac{1}{100}$ gramme-molecule). A second series of experiments was performed with a solution of crystallised barium chloride (1 litre = $\frac{1}{217}$ gramme-molecule) to which small quantities of above-mentioned solution of baryta were successively added. The difference between the ordinates observed and those calculated, on the supposition that only a neutral compound is formed and that the system should consist only of two straight lines, amount to as much as about 1 per cent. of their value. The curve becomes a straight line more quickly in the case of acid than of alkaline solutions.—P. J. H.

Lecture Experiment to show the Absorption of Hydrogen by Palladium. T. Wilm. *Ber.* 1892, **25**, 217—219.

3—4 grms. of palladium sponge, made by heating palladium ammonium chloride ($\text{PdCl}_2 \cdot 2\text{NH}_3$) first in the air and then in hydrogen, are placed in a bulb blown at the end of a U-tube. The tube is connected on the one side with a Kipp's hydrogen generator, and on the other with a glass tube provided with a good stop-cock, special care being taken that the connexions are tight. Pure dry hydrogen is then passed through the tube, the exit tap being open, whilst the bulb of the U-tube is heated by an ordinary burner. In order to remove the water formed in the tube the two limbs are also carefully heated. After the hydrogen has passed through the tube for a considerable time, and long after the whole of the air has been replaced, it is found that the gas coming through the exit tap only burns intermittently, unless the tap be turned when the increased pressure in the tube allows a small flame to burn continuously. If now the heating be discontinued and the exit cock closed, the occlusion of the hydrogen will be shown by the fact that the current of hydrogen continues to pass through the wash-bottles. When no more gas is absorbed the palladium is again heated and the exit tap opened (the current of hydrogen being still allowed to pass) when the issuing hydrogen burns with a long continuous flame, which immediately goes out when the heating is discontinued. By this means the occlusion of the hydrogen can be readily shown to a large audience.—C. A. K.

New Books.

GAS WORKS. Their Construction and Arrangement, and the Manufacture and Distribution of Coal Gas. Originally written by SAMUEL HUGHES, C.E. Re-written and much enlarged by WILLIAM RICHARDS, C.E. Eighth edition, revised, with Notices of Recent Improvements. London: Crosby Lockwood and Son, 7, Stationers' Hall Court, Ludgate Hill. 1892.

8vo volume bound in cloth, with frontispiece representing plan of Gas Works for town of 10,000 inhabitants, Preface, Table of Contents, Subject-matter covering 410 pages, and an Alphabetical Index. The text is illustrated by 75 well-executed wood engravings. The subdivision of the subject into chapters is as follows:—Chapter I. Historical Sketch of Gas Lighting. II. The Chemistry of Gas Lighting. III. The Composition of Coal Gas. IV. Coal used in Gas Making. V. Carburation. VI. General Construction. VII. Retorts and Retort Settings. VIII. The Hydraulic Main and Valves. IX. The Exhauster. X. The Purification of Gas. XI. Gas Holders. XII. The Station Meter. XIII. The Photometer. XIV. The Governor, Regulator, Pressure Gauge, and Pressure register. XV. Application and Manufacture of Residual Products. XVI. Distribution. XVII. Consumers' Meters. XVIII. Burners and Glasses. XIX. The Various Applications of Gas for Heating, Cooking, and other Purposes. XX. Gas Explosions. XXI. Various Methods of Producing Light. XXII. The Various Con-

trolling Influences which affect the Quality and Volume of Gas. XXIII. Public Lighting. XXIV. General Remarks. XXV. The Sliding Scale. The price of the work is 6s.

FARMYARD MANURE. Its Nature, Composition, and Treatment. By C. M. AIKMAN, M.A., B.Sc., F.R.S.E., &c., Lecturer on Agricultural Chemistry, West of Scotland Technical College. William Blackwood & Sons, Edinburgh and London. 1892.

SMALL 8vo. volume, bound in cloth, limp. It contains Preface, Table of Contents, Introduction, and 65 pages of Subject-matter. There is no Alphabetical Index, but the Table of Contents is both clear and well arranged. The sub-division of the matter is as follows:—**INTRODUCTION.** On what fertility of soil depends. Function of manures. **FARMYARD MANURE.** Solid Excreta. Urine. Horse manure. Cow manure. Pig manure. Sheep manure. Methods of calculating the amount of manure produced on the farm. Fermentation of farmyard manure. Analyses of farmyard manure. Comparison of fresh and rotten manure. Methods of application of farmyard manure to the field. Value and function of farmyard manure.

The price of the book is 1s. 6d.

CHEMISCH-TECHNISCHES REPERTORIUM. Uebersichtlich geordnete Mittheilungen der neuesten Erfindungen, Fortschritte und Verbesserungen auf dem Gebiete der Technischen und Industriellen Chemie, mit Hinweis auf Maschinen, Apparate, und Literatur. Herausgegeben von DR. EMIL JACOBSEN, 1891. Erstes Halbjahr. Zweite Hälfte. Berlin, 1892. R. Gaertner's Verlagsbuchhandlung, Hermann Heyfelder, S.W. Schönebergerstr. 26. London: H. Grevel and Co., 33, King Street, Covent Garden.

THE Repertorium of Chemical Technology for the latter quarter of the first half of 1891 has just appeared. Its pages run from 153 to 307, and the following branches of chemical industry are treated of:—Food Stuffs; Paper; Photography; Residuals, Manures, Disinfection, and Sanitation; Soaps; Explosives; Preparation and Purification of Chemicals; Chemical Analysis; Apparatus, Machinery; Electro-Technology; Thermo-Technology, and Appendix. Special Preparations, Adulterants of Trade Products, &c. New Books. The text is interspersed with numerous woodcuts representing apparatus and plant.

FUELS, SOLID, LIQUID, AND GASEOUS. Their Analysis and Valuation. For the Use of Chemists and Engineers. By H. JOSHUA PHILLIPS, F.I.C., F.C.S. Second Edition. Revised and Enlarged. London: Crosby Lockwood and Son, 7, Stationers' Hall Court, Ludgate Hill, E.C. 1892.

SMALL 8vo. volume, bound in cloth. It contains Prefaces, Table of Contents, and Text covering 108 pages. The pages are illustrated with 14 wood engravings, and the work concludes with an Alphabetical Index.

The work is subdivided into the following branches:—**METHODS OF ANALYSIS:** Characteristics of Fuels. Estimation of Ash and Moisture; of Coke and Volatile Matter; of Sulphur, Nitrogen, Carbon, Hydrogen, and Oxygen. Estimation of Specific Gravity and Flash-point. Analysis of Gaseous Fuel. Ashes of Fuels. **METHODS OF VALUATION:** Calorific Values. Tables of Practical Results and Analyses. In his Preface to the Second Edition the author proclaims that in 12 months he has been called on for a second edition by a demand from both chemists and engineers. The enlargement is considerable and the improvements very manifest. Thus, amongst the additions, methods for the analysis of the ashes of fuels, practical methods for obtaining the calorific value and specific gravity of gaseous fuel, and for the determination of sulphur in gaseous fuel, &c. &c.

The price of the work is 3s. 6d.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

SWITZERLAND.

Note.—Quintal = 220·4 lb. avoirdupois. Franc = 9⁶/₁₀d.

The following decisions affecting the classification of articles in the Swiss Customs tariff were given by the Swiss Customs authorities in the month of March last:—

Oil of amber.—Category 13. Duty, 10 francs per quintal.

Sulphate of benzidine.—Category 46. Duty, 60 cents. per quintal.

Electric accumulators of every kind and detached pieces of the same, such as plates, fitted or not, frames, &c.: telephones and detached parts of the same, such as boxes, registers, &c.—Category 215. Duty, 6 francs per quintal.

Plates (frames), of lead, perforated, for electric accumulators are removed from Category 240 to Category 215, and now pay a duty of 6 francs per quintal.

FRANCE.

Note.—Kilog. = 2·204 lb. avoirdupois. Franc = 9⁶/₁₀d.

The following decisions affecting the classification of articles in the new French Customs tariff have recently been given by the French Customs authorities:—

Myrobolams, properly so-called, dry, whole or crushed, and libi-divi or divi-divi.—Category 156. Free of duty.

Dry colours composed of sulphate of barytes or any similar substances, coloured with a small quantity of a derivative from coal tar (3 per cent. at the most).—Category 310. Duty, 5 per cent. *ad valorem*.

Bone-glue, English glue, bone-size (product of a gelatinous base used in the preparation of tissues and specially of Amiens cotton velvet).—Category 313. Duty, 6 francs per 100 kilos.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

THE SICILIAN SULPHUR INDUSTRY.

The French Consul at Messina has recently addressed a report to his Government upon the condition of the sulphur industry in Sicily. He states that the production of sulphur in 1891 showed a decided falling off as compared with 1890, the amounts being 4,499,479 cantars (13 cantars = 1 ton) in the former and 3,817,053 cantars in the latter year. This diminution is owing in great measure to the fact that the large mines which represent three-fourths of the production worked with exceptional activity at the time of the last crisis, in order to distribute the general expenses over a much larger product, with the result that at the present time they are unable to show an increased out-turn, and in some cases there is a very decided diminution in the amount produced. Again, no new workings were begun during the period the crisis lasted.

As regards the smaller mines, which are very numerous, these show no increase in production, while a large number have gone out of working altogether. In considering the question of the diminution in the supply of sulphur, account must also be taken of the variation in the number of hours devoted by the workmen to labour in the mines. When prices were low the Sicilian labourers were obliged to work like persons engaged in other industries, six days a week and as many hours as was found necessary, in order to extract the ore in sufficient quantity to enable them to draw an ordinary wage. With the enhanced value of the product came an increase in the price of labour, the workmen then

commenced to work by the half-day with one day a week off, and then a reduction of the hours of labour was effected, to the extent that about 24 hours' work a week is now about all that an ordinary labourer in the sulphur mines performs. Consequently, as the working mining population is limited and is composed of special workmen, the production becomes more and more restricted.

Among other causes of diminution in the output may be mentioned the placing under cultivation of land productive of ore of an inferior quality, and which the owners thought it more to their advantage to cultivate than to work for sulphur, and the imposition of a new tax of 60 centimes per kilogramme upon the manufacture of mining powder.

The very gravest apprehensions are felt for the future of the sulphur industry in Sicily. It is expected that for some years to come the production will be to a great extent limited. In the first place a restriction of labour appears to be threatened by the action of the Italian Legislature affecting the employment of children. Of the latter many of 11 to 12 years of age are engaged in the mines carrying ore, and owing to the absence of capital it will be difficult for the mine owners to replace their labour by machinery.

The depth of the mines is continually increasing, particularly in the case of those mines in which shafts are sunk vertically, and these latter are by far the most important and the richest. With an increase of depth, difficulties also increase, these consisting of more improved methods of extraction, greater ventilation, and the employment of larger pumps, all of which require considerable outlay. It will, therefore, in the opinion of M. de Lalande, be some years to come before the average production of the last 10 years is again reached.

According to the chief engineer of the Sicilian mines, the falling off in the production of sulphur in 1891, as compared with 1890, amounted to over 58,000 tons, and this was owing to the wild speculations in Sicily, especially those which were engaged in between December 1890 and May of the following year, and which ruined many of those engaged in the sulphur industry. At this period also throughout the world (for Sicily furnishes nearly nine-tenths of all the sulphur used) merchants, agriculturists, and manufacturers, in fact consumers of all kinds, rather than purchase at the then exorbitant prices, exhausted their stocks, and if it became necessary to buy they confined their orders to a supply only just sufficient to carry them on from day to day.

The exhaustion of the stocks of sulphur in foreign countries brings into relief the fact that the falling off in the demand is more accentuated in countries where sulphur is more particularly employed for agricultural purposes, and especially in the treatment of vines, as, for example, in France and Greece, than in countries like the United States, England, Austria, and Sweden, where sulphur is used chiefly in the various industries, and is therefore the object of frequent and direct purchases. From the United States, however, evidences are forthcoming of a tendency to substitute for certain industrial purposes pyrites for sulphur, but this substitution can only be effected slowly and in factories having had the time to renew their plant, and there is little probability of all of them acting in this respect simultaneously. This abandonment of sulphur in certain respects would find its compensation in the employment of the article by new industries or by the application of improved processes. In this connexion mention may be made of the methods now being attempted in Germany of extracting fatty substances and oils by the action of liquid sulphuric acid, and if, as is claimed, this system is superior, so far as results are concerned, to all those hitherto in vogue, it points in the future to a fresh outlet for sulphur and one not without some importance.

M. de Lalande, speaking of the present condition of the sulphur market in Sicily, says that it is by no means unsatisfactory; the production certainly shows a tendency to restriction, but this in his opinion is due less to an absence of confidence than to the want of new outlets. Capital is wanting, labour is dear, and miners difficult to find, but in his opinion the outlook is far from discouraging, as the sulphur beds in Sicily still enjoy the reputation of being the finest in the world.—*Board of Trade Journal*.

INDUSTRIAL DEVELOPMENT AND FIELDS FOR CAPITAL IN MEXICO.

A report has recently been presented to the French Government by the French diplomatic agent in Mexico, upon the undeveloped mineral and agricultural resources of that country. From this report the following information has been extracted:—

The richness of the soil of Mexico exceeds anything that can be imagined. In a relatively small area all climates and products are found. It is not necessary to travel great distances in order to pass the region of wheat, of the beet, oak, and pine, of the vine, olive, and orange, and of the sugar-cane, coffee, and vanilla. The transitions are rapid. The traveller who passes through the torrid region of Vera Cruz in the morning may at nightfall enter into the region of eternal snows.

The absence of means of communication has paralysed the efforts of numerous agriculturists, but this disadvantage is disappearing daily; the railways are extending and branching out rapidly throughout the country.

The wealth of the subsoil of Mexico is enormous; silver, gold, copper, iron, lead, tin, and all other minerals abound everywhere. The volcanoes contain immense quantities of sulphur; the petroleum wells and salt deposits present favourable openings for capital.

The abundance of raw materials and the cheapness of labour favour the establishment and development of industries. The raw materials cost little; there is no lack of coal mines, the working of some of them having already given satisfactory results. In Mexico, therefore, not only could the metallurgical industries be profitably established, but also weaving, sugar, dyeing and other industries. These industries certainly have at the present time some representatives, but they are by no means sufficient for such an extended market.

There is also a lack of saw and wood mills, and paper, oil and soap factories; there are no tanneries, glassworks, distilleries, factories of chemical products, for which some lakes and volcanoes offer inexhaustible quantities of valuable products.—*Ibid*.

ARGENTINE REPUBLIC.

Drug Imports.

Among the imports of pharmaceutical goods into the Argentine Republic in 1890, the following items are of interest. (The first number, except where otherwise stated, denotes the quantity in kilos.; the next, in parentheses, the value in dollars):—Sulphuric acid, 1,246,376 (62,219); linseed oil, 452,237 (80,908); spirits of turpentine, 437,261 (57,442); varnish, 98,253 (78,600); bicarbonate of soda, 360,374 (25,624); carbonate of potassium, 16,873 (2,531); carbonate of soda, 328,195 (12,715); paint, in powder, 1,958,916 (149,488); ditto, prepared, 2,011,057 (189,749); essential oils, — (43,860); specifics for curing sheep-scab, — (269,488); phosphorus, 16,079 (16,249); gums, 139,011 (33,279); iodide of potassium, 643 (3,215); scap, common, 36,930 (10,642); ditto, perfumed, 42,504 (22,784); malt, 2,902,798 (290,279); prepared medicines, — (273,560); perfumery, — (257,624); pharmaceutical products, — (65,595); chemical products, — (417,785); soda ash, 2,581,048 (77,430); caustic soda, 132,806 (6,640); sulphate of quinine, 19 (760); druggist's utensils, — (182,264); glass bottles, 238,624 dozen (71,584); scientific instruments, — (88,311); gutta-percha articles, — (92,254).

Drug Exports.

The exports from Argentina connected with the drug trade are mostly of the animal kingdom. They total as follows:—Extract of beef, 187,566 (375,132); glycerin, 161,306 (46,522); pepsin, 13,830 (20,745); honey, 52,799 (9,004); beeswax, 6,798 (3,059).—*Chemist and Druggist*.

MAURITIUS.

Drugs.

Last year Mauritius imported 1,385,100 rs. worth of chemical products, mostly sulphate of ammonia and nitrate of potash, from Australia and India, but also including 302,197 rs. worth of drugs and medicinal compounds from England and France.

Soap.

Ten years ago nearly all the soap used in Mauritius came from France and, as the consumption is over 1,000 tons a year, this was a trade worth cultivating. But since then France has been deprived of nearly half her trade by Australia and by the Seychelles islands, in which latter group a soap-works has recently been established.—*Ibid.*

MOROCCO.

British Trade.

The share of Great Britain in the imports of Mogadore is very satisfactory—viz., 55 per cent. in 1891 against 52 per cent. the year before. The remainder of goods imported was mostly from France.

Foreign Goods via London.

Although these figures are eminently gratifying, yet, on examining the subject more closely, we find that, in the import table at any rate, they are liable to some discount, since there is no doubt that for some years prior to 1890 a considerable quantity of goods of German and some of Belgian origin had been imported *via* London in English steamers, and therefore inclusively swelled the total from Great Britain. Even now some German merchandise sometimes comes in on English steamers.

Exports to Germany.

The export trade to Germany commenced in 1890 with the opening of the "Woermann" and "Atlas" lines of steamers. The first year the steamers took, among other goods, beeswax, 720*l.*; cumin seed, 507*l.*; gums, 900*l.*; olive oil, 29,248*l.*; orris-root, 36*l.*, and sesame, 33*l.* In 1891, beeswax, 2,304*l.*; cumin, 24*l.*; gums, 2,250*l.*; oil, 10,710*l.*; orris-root, 224*l.*; rose-leaves, and sesame, 48*l.*

Gums.

The gum exports from Mogadore were as follows:—

Gums.	1891.		1890.	
	Tons.	£	Tons.	£
Brown.....	85	6,375	48	3,600
Amral.....	33	1,056	In brown.	
Senegal.....	174	13,050	130	14,390
Sindarac.....	128	11,850	156	11,700

Olive Oil.

The shipments of olive oil were affected both by shorter supply and lowness of prices, especially in London, the total for the year amounting to 43,850*l.* against 138,720*l.* for the previous one. The value was thus divided: Great Britain, 8,960*l.*; France, 10,955*l.*; Germany, 10,710*l.*; Portugal, 2,905*l.*; Spain, 490*l.* In the middle of March there was a considerable quantity of Government oil in store, awaiting favourable advices from European markets.

—*Ibid.*

ITALY.

British Trade.

The following figures relate to the exports from and imports into Italy of pharmaceutical goods from Great Britain and her colonies:—

Imports into Italy.	1890.	1891.	Difference.
	Cwt.	Cwt.	Cwt.
Acids	8,640	6,388	— 2,252
Potash and caustic soda (impure).....	136,006	135,090	— 916
Alkaloids	33	72	+ 39
Oxides	17,344	20,440	+ 3,096
Carbonates	59,766	68,460	+ 8,694
Chlorides	76,482	38,406	— 38,076
Nitrates	40,554	14,700	— 25,854
Sulphates.....	258,412	308,596	+ 50,184
Other chemical products.....	25,698	32,662	+ 6,964
Quinine and bark.....	9,696	3,198	— 6,498
Gums and resins.....	21,144	37,368	+ 16,224
Soap.....	9,511	8,550	— 961

Exports from Italy.	1890.	1891.	Difference.
	Cwt.	Cwt.	Cwt.
Boric acid	34,050	28,272	— 5,778
	Lb.	Lb.	Lb.
Alkaloids	5,180	701	— 4,479
	Cwt.	Cwt.	Cwt.
Tartar and lees of wine.....	101,782	151,148	+ 49,366
Orange and lemon juices....	42,388	15,144	— 27,244
Liquorice, aloes, &c.....	12,882	12,182	— 700
Soap.....	19,018	21,156	+ 2,138

—*Ibid.*

MINERAL DISCOVERIES IN GREECE.

The mineral wealth of the island of Milo has just been increased by the discovery of mines of barytes containing, it appears, a large quantity of silver.

According to the French Consul at Syra, explorations have been made in the localities of Mirovilia, Pikrondon, Castagnia, and at Teriades on the promontory of Vani to the north-east of the island. Everywhere the results have exceeded the highest anticipations.

At Mirovilia there have been opened six galleries of a total length of 104 metres, and four wells of 11 metres each. Analysis has established the proportion of from 300 to 1,900 grms. of silver per ton of barytes.

At Pikrondon pits to a small depth have been sunk from which 720 metric centners of barytes have been extracted. The proportion of silver is from 200 to 250 grms. per ton.

At Castagnia the barytes extracted from three pits contains the same proportion of silver.

At Triades five horizontal galleries have been sunk, and the barytes extracted in this locality contains 300 grms. of silver per ton.

Further, in other places pieces of barytes have been gathered in the open trenches which have given up to 10,000 grms. per ton.

The mass of barytes at Milo is estimated at 12,000,000 tons. Supposing that 200 tons were extracted daily it would require 700 years to exhaust it. It is recommended that foundries of the "Angustin" type, similar to those in use in Hungary, should be established in the localities mentioned above, and more particularly at Kannari and at Pigadakia, where water is to be had in plenty. These two localities are also sufficiently near to the sea to permit ships of large tonnage to effect loading.—*Board of Trade Journal.*

EXPORTS OF HENEQUEN FROM MEXICO.

The French Consul at Vera Cruz, in a report upon the Mexican export of henequen in 1891, says:—

The weight of henequen exported from Mexico in 1891 was 113,263,519 lb., valued at 5,996,044 piastres. In 1890, the quantity and value were respectively 97,959,373 lb. and 5,007,562 piastres, and in 1889, 87,839,783 lb. and 8,783,978 piastres.

It therefore appears that production has increased to a large extent in 1891, compared with the two preceding years, but the article having kept at a low price, which was lower still in 1891, it results that the value exported in 1889 was superior to that which is represented by the exports for the two following years, although the quantity exported has been less.

In fact the average price in 1889 was 10 centimes of a piastre per pound, against 5.1 cents. in 1890 and 5.2 cents. in 1891. The average price for last year is therefore slightly higher than that for 1890, a fact which should be taken into account as well as the increase shown by the quantity exported.—*Ibid.*

GENERAL TRADE NOTES.

QUININE AND JAVA CINCHONA.

Chem. and Druggist, 40, 589–590.

Full statistics are given of the estimated crop of Java cinchona for 1892. The statistics show that of the 115 plantations known to exist in the island two have been abandoned since last year, while on three others all the trees have been uprooted. These three plantations only produced an aggregate of 120,000 lb. of bark, or less than 3 per cent. of the total production—a fact which disposes of the assertion that there has been a general uprooting of trees in consequence of the low prices which have ruled. Moreover, nearly all the uprooted cinchona averaged only 3 to 3½ per cent. of quinine sulphate, a yield admittedly too low to hold out any prospect of successful competition in the future. On the other hand, twenty-six plantations have either not yet come into bearing at all or only yield insignificant quantities, while six others, though still in existence and ready to ship bark under more favourable circumstances, did not harvest any last season. These figures indicate that there is plenty of reserve stock in the island to fall back upon when the market improves. Another important feature of the return is that the quinine value of the bark on almost all the large estates is increasing. The manufacturing bark from Java, which averaged about 3½ per cent. not long ago, will next season represent an average value of nearly 5 per cent. in sulphate of quinine, and that proportion is likely to be still further increased later on. The main interest of the statistical returns, however, lies in the fact that, for the first time in the history of the Java cinchona industry, they presage a falling off, positive as well as relative, in the shipments from the island. If the unit remains where it is now, the compilers expect the quinine output of the island to be fully 10 per cent. less than last season, and even if the unit should improve to 1½d. or 1¾d. per lb., it is likely to fall below that of 1891 by 1 per cent. or thereabouts. Private advices state that the actual shipments will almost certainly fall below the minimum mentioned in the returns, unless indeed, in the unlikely event of a considerable improvement in prices.

The position of the Java planters to-day resembles that of their Ceylon colleagues in 1886 in this respect—that the excessive feeding of the European bark-market is beginning to produce the inevitable reaction—but the situation is different from that in Ceylon six years ago, first, inasmuch as there is in Java a heavy supply of rich bark to fall back upon; secondly, because the Java growers have taken to heart the lesson that the indiscriminate production of low-grade, quickly-growing barks does not pay; and, finally, because they have not, as the Ceylon growers had at the time, looming before them the spectre of a new and rapidly-growing source of production the advent of which they are bound to forestall at all hazards. There is no important source of supply behind the Java planters.

The threatened falling off in the production of Java cinchona-bark would, no doubt, under ordinary circumstances, make itself felt in the quinine market. But that market has been unhinged to such a degree by speculative sales, that the effect of the laws which usually govern the fluctuations of manufactured products may be retarded for a considerable time. There is certainly no indication yet of any upward movement in quinine, though the signs which would warrant such a tendency are slowly accumulating at the horizon.

ON THE PRODUCTION OF SUGAR IN BRITISH INDIA.

Chem. Zeit 1891, 15, 1584.

According to statistics received by the Indian Government from a certain firm, the average yield of sugar is one ton per acre, and it is of very poor quality; whereas in the West Indies the sugar planter obtains two tons per acre. The explanation of this small yield is that, in India, with the exception of three large sugar factories in Madras, only small plantations exist, and the 2½–3 million acres devoted to the industry are almost exclusively cultivated by natives under conditions which render the management of large sugar refineries impossible. Some years ago the native planter was still using primitive methods which had been in vogue for centuries, but the above-mentioned firm has since introduced a cheap, easily transportable, crushing mill of simple construction, and this has been such a success that at present upwards of 200,000 are in use, and a planter who formerly cultivated 30 acres now cultivates 600 acres, and obtains a better product. Improved forms of evaporating apparatus have also been introduced.

—A. R. L.

THE SISAL GRASS OF YUCATAN.

One of the most remarkable vegetable products known, and one of the most valuable resources of Yucatan, says the *Mexican Financial Review*, is its sisal grass. It grows in long, narrow blades, often to the length of four or five feet, and these, when dry, curl up from side to side, forming a flexible string, stronger than any cotton cord of the same size ever manufactured. It is in great demand among florists and among manufacturers of various kinds of grass goods; but as soon as its valuable properties become known it will have a thousand uses now undreamed of. Ropes, coils, lines of any description and any size may be manufactured of it, and a ship's cable of sisal grass is one of the possibilities of the future. It is almost impervious to the action of salt water, and is not readily decayed or disintegrated by moisture and heat, and will, in time, prove one of the most valuable productions of Mexico. It takes its name from the port of Sisal in Yucatan, through which it was formerly exported.—*Ibid.*

CANADIAN PLATINUM.

It has long been known that platinum had been found in the province of Quebec. In the Report of the Geological Survey for 1851–52 it is stated that Dr. Hunt had detected native platinum in some of the gold washings of the Chaudière district. In the province of Ontario platinum has been discovered in the Sudbury district. It there occurs in combination with arsenic, forming the mineral sperrylite, which is of great interest, as it is “the first mineral yet found containing platinum as an important constituent other than the natural alloys with various metals of the platinum group.” So far as can be learned, no effort has yet been made to utilise sperrylite as a source of platinum, but at present it brings a high price as a mineralogical curiosity.

Canadian platinum ore, as a commercial article, is entirely the product of British Columbia. In association with alluvial gold it has been met with in a number of the streams of that province. At present the most important platinum-bearing district of British Columbia, as well, indeed, as of North America, is that of the Tulameen or North Fork of the Similkameen river. Placer mining in this district yields both gold and platinum, the latter being found, like the gold, in grains and small nuggets. A notable quantity of platinum has already been obtained from this district. One firm in the United States claims to have purchased within the last year or two fully 2,000 oz.

of British Columbia platinum, and it is well known that a portion of the yield of this district has found its way to the London market.

An increase of output may be expected, as the Tulameen Hydraulic and Improvement Company has made preparations to begin hydraulic mining on a large scale with the advent of spring. Mr. R. G. Tatlow, a member of this company, informs me that his company has erected a saw-mill having a capacity of 5,000 ft. per diem, and has constructed about two miles of flume, 5 ft. at base, 20 in. high, on sills placed on solid bed about 7 ft. wide, and having a grade of $\frac{1}{2}$ in. in 12 ft. The water is taken from Eagle Creek, about 14 miles above Granite Creek, the only creek capable of giving the necessary quantity of water and pressure. In addition to this flume, the company has on the ground and ready for work about 400 ft. of iron pipe and a monitor, which, where work is to be commenced, will work with a pressure of 900 miners' inches and a drop of about 160 ft. Mr. Tatlow also states that the largest yield of platinum appears to have been in the vicinity of and below Eagle Creek, where the yield has been about two parts of gold to one of platinum.

Two samples of this Tulameen ore contained 69.28 per cent. and 72 per cent. platinum. It is really a very complex alloy of platinum with a number of the comparatively rare metals of this group, such as palladium, iridium, and notably an alloy of osmium and iridium, known as osmiridium, which, in grains of proper size and form, is used for pen-points. This ore is worth to-day about 5.50 dols. per oz. troy. The price is very unsteady, being determined by the demand for the metal and by the state of affairs in Russia, the principal producer of the ore.

An interesting statement in connexion with the metallurgy of platinum was made by the President of the Chemical Section of the British Association at the meeting of last year. It is to the effect that one firm of refiners in London have such facilities that $2\frac{1}{2}$ ewt. of platinum may be melted in a single charge, and that the same firm, in a single operation, extracted a mass of palladium valued at 30,000*l.* from gold-platinum ore actually worth more than a million sterling!—*Engineering and Mining Journal*.

RUSSIAN SUNFLOWER OIL.

The sunflower has been known in Russia for many years but only in certain districts has it been cultivated on a large scale. The first cultivation of sunflower-seed for mercantile purposes in Russia began in 1842, in the village of Alexievka, district of Berutshinsk, government of Voronezh. That province is even now the chief district in European Russia for the growing of the sunflower. From there the cultivation of sunflowers spread to the adjacent governments of Tambov and Saratov, where there are extensive cultures owned by the town of Saratov itself. The people of the governments of the Don, Simbirsk, and Samara, are more or less engaged in this trade. Two kinds of sunflower are known, one with small seeds used for the production of oil, and the other with large seeds consumed by the common people in enormous quantities as a dainty. In a district where the seed is cultivated on a large scale, and the plant has been continually grown on the same soil for many years in succession, the sunflower has become subject to a disease called *Puccinia dioscorearum*. Owing to this disease the sunflower crops have been rather poor in the government of Voronezh for the last ten years, and the cultivation has, therefore, abated somewhat in this locality. The sunflower-seed is used principally for obtaining an oil which has superseded all other vegetable oils in many parts of Russia. In general, the cultivation of the sunflower in Russia is considered to be very profitable. At the average yield of 1,350 lb. per acre, and at the average price of $\frac{3}{4}$ d. per lb., the farmer receives an income of about 4*l.* per acre. This income can be increased in districts where the grower himself is engaged in producing the oil from the seed. However, oil-mills are very rare in the villages, the farmers selling their seed to the oil producers. In the seed-growing district of Saratov there are only 34 village oil-mills, producing oil worth 8,000*l.* annually, whereas in the town of Saratov 90,000*l.* worth of oil is manufactured annually. The substance remaining from the oil manufacture, or the

sunflower cakes, being used as cattle food, is also a valuable product. These cakes, however, have a comparatively small demand in Russia, and are largely exported to foreign countries, principally to Germany and England. The sunflower-shells, being used for heating purposes, form an article of trade in several districts. The seed-cups are used as food for sheep. Of the different kinds of sunflower seed in Russia—some white or grey, some brown with white or grey stripes, some quite black, dyeing the cells a dark violet colour—the grey and striped seeds are preferred, as they appear to be much cleaner and handsomer, and therefore command a higher price, especially for the purpose of raw consumption by the common people. The black seed, owing to its dark colouring matter, is generally avoided. All these seeds appear in the market divided into two sorts. The larger kind, containing less oil, is the cheaper; the smaller, producing more oil, is sold to the oil manufacturers, and is much more expensive. The latter seeds are flat and oval, like coffee beans, and are considered the best for this industry.—*Chemist and Druggist*.

THE CORNISH ASSAY.

Last year the Anaconda Mining Company took a step in advance by declining to sell copper matte in England upon English terms and deductions, so far as the settlement was concerned, bills being made out and settled for at so many pence for so many pounds of fine copper. The result was not reached without some grumbling on the part of English smelters, and now Mr. Haggin has made another further and radical advance in declining to sell any longer by the Cornish assay, insisting upon the wet analysis, with the allowance of 1.3 units, customary in this country. Upon these terms 1,800 tons of argentiferous matte were purchased by a large Liverpool house last month, followed by a second purchase of 600 tons by another smelter. Since then large contracts have been made on the same basis, amounting to many thousands of tons. It is but a step further now to compelling all foreign buyers to accept American assays and weights, since American methods of assay and settlement are conceded. In the present state of the market for furnace material it requires the concurrence of only two or three American producers to obtain this concession. As is well known, some of our largest copper miners never sell on any other basis.—*Engineering and Mining Journal*.

WIRE GLASS.

Under the name of wire glass a new invention has been brought on the market by a Dresden firm, the *Actien-Gesellschaft für Glasindustrie vorm. Friedr. Siemens*, says *Iron*, which marks an important development in the glass-making industry. The process of manufacture consists in furnishing glass in hot plastic condition with a flexible metallic layer, iron wire netting, for instance, which is completely inclosed by the vitreous substance and effectively protected against exterior influences, as rust, &c. The new glass possesses much greater resisting power than the ordinary material, and is, it is claimed, indifferent to the most abrupt changes of temperature. A proof of its toughness and durability is the fact that it may, in a highly heated state, be sprinkled with cold water without being materially damaged. The glass is specially adapted for skylights, the powerful resisting qualities of the material enabling the usual wire protectors to be dispensed with. As wire glass cannot be cut by the diamond, except under the application of great force, and cannot be broken without creating considerable noise, the substance is claimed to be, in a measure, burglar proof. Wire glass has also been successfully applied to the manufacture of hollow glass ware, it being particularly suitable for making glass vessels which have to withstand a high pressure or be subjected to rough usage. The new material is at present being manufactured in sheets of 8 mm. thickness and upwards.

ALKALI WORKS, &c. ACT AMENDMENT BILL.

On Friday, May 6th, a meeting, called by the Council of the Society of Chemical Industry, was held at the Society's offices, to consider the Alkali Works, &c. Act Amendment Bill recently introduced by the President of the Local

Government Board. The following gentlemen were present : Sir H. E. Roscoe, M.P., F.R.S., Mr. J. T. Brunner, M.P., Mr. J. C. Stevenson, M.P., Mr. A. E. Fletcher, Her Majesty's Chief Inspector under the Act it is proposed to amend, Col. D. Gamble representing a committee of Lancashire and Cheshire manufacturers, Messrs. Newlands, Crowder, Howard, Redwood, and Tyrer. The following resolution was passed :—"That this meeting of members of the Society of Chemical Industry, called by the Council of the Society, and comprising chemical manufacturers engaged in trades affected by the existing Act and the proposed Bill, adopts the resolution of the meeting of chemical manufacturers held yesterday in Liverpool, to the effect that the proposed Bill is not comprehensive enough in its scope, and that to be satisfactory provision should be made for the inspection of all works evolving certain specified noxious gases with the view of ultimately fixing a definite limit; also that the passing of the proposed Bill will render it difficult to pass another more comprehensive measure in the near future."

A meeting of the Chemical and Allied Trades Section of London Chamber of Commerce, states the *Chemical Trade Journal*, was held at the offices of the Chamber on Friday, 27th May, to consider the effect on chemical and allied industries of the same Bill. It was thought that this measure, if passed, would be productive of grave injury to many of the smaller industries, and might have the effect of driving them abroad altogether. Further, it was believed that the real offenders would not be touched by the present Bill, inasmuch as dyeworks and works of a similar character which give off noxious vapours, purposely carry on at times part of their process of manufacture during the night, with the result that any neighbouring

chemical or alkali works usually is credited with creating the nuisance complained of. It was reported that the chemical manufacturers of Liverpool, the Society of Chemical Industry, and the Coal Tar Distillers' Association had already taken steps to oppose the Bill, and it was resolved to second these efforts by a petition to the House of Commons. A petition has since been lodged opposing the Bill on the following grounds :—

(a.) That the extension of the provisions of the Alkali Act of 1881 to the works set forth in the schedule to the Amendment Bill would be a serious hindrance to trade, by reason of the restrictions proposed, and that in the case of many of the works it would seriously hamper them in their struggle with the increasing competition of foreign manufacturers, thus tending to drive these industries abroad.

(b.) That the Bill is entirely unnecessary inasmuch as where grievances are alleged the complainants have very ample facilities and powers to prosecute under the Local Government Acts.

(c.) That if further legislation is deemed necessary it is submitted that the present Bill is not sufficiently general, as the schedule thereto does not include many works which in their processes of manufacture are liable to emit gases at least as offensive and injurious as the works which form the subject of the proposed legislation.

(d.) That the inclusion of certain works and the exclusion of others similarly conducted and equally requiring inspection—if such is necessary—in the schedule to the Bill, can only result in anomalies, inconveniences, and difficulties, which would be a source of general dissatisfaction.

(e.) That any Bill affecting the industries scheduled should contain provisions for the inspection of *all* works evolving certain specified noxious gases.

MINERAL PRODUCTION OF PRUSSIA.

The production of the mines and metallurgical works of Prussia in 1890 and the two preceding years, according to the *Zeitschrift für das Berg-, Hütten-, und Salinenwesen im Preussischen Staate*, Band xxxix., was as follows :—

THE SALE OF FOOD AND DRUGS ACT.

The following is the text of the Bill introduced into the House of Commons last February, by Dr. Cameron, M.P., and only just printed:—

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:—

1. The provisions of the Sale of Food and Drugs Act, 1875, and of any Act amending the same, shall apply to and include every wholesale trader or manufacturer of any article of food or drug who shall sell to the prejudice of the purchaser any article of food or drug which is not of the nature, substance, and quality of the article demanded by such purchaser; and the 17th section of the said Act shall be read as if the words "whether by wholesale or" were inserted between the words "on sale" and the words "by retail" in the said section.

2. The 25th section of the said Act shall be and is hereby amended by the deletion of the word "written" before the words "warranty to that effect," and every wholesale trader or manufacturer of any article of food or drug, or other person who in the course of trade shall sell to any person any article of food or drug, with intent that the same may be resold by retail in the state in which it is purchased from him, shall, unless he has in writing informed the purchaser to the contrary, be deemed, for the purposes of the said Act, to have given a warranty to the

person purchasing from him that such article of food or drug is of the nature, substance, and quality demanded by such purchaser.

3. In any proceedings under the principal Act having reference to the sale of "margarine" as defined by the Margarine Act, 1887, it shall be a good defence to prove that the sale was made in conformity with the regulations of the said Margarine Act, 1887, and in the case of proceedings in Scotland under the said Margarine Act, the 33rd section of the Food and Drugs Act, 1875, shall be held to be added to the sections 12 to 28 inclusive incorporated in section 12 of that Act.

4. In determining whether an offence has been committed under section 6 of the principal Act, by selling to the prejudice of the purchaser coffee not adulterated otherwise than by the admixture of chicory, it shall be a good defence to prove—

(a.) Where the admixture of chicory does not exceed 50 per cent., that the seller delivered with or on such mixture a notice by a label distinctly and legibly written or printed bearing the words "This is sold as a mixture of coffee and chicory."

(b.) Where the admixture of chicory does not exceed 75 per cent., that the seller delivered with or on such mixture a notice by a label distinctly and legibly written or printed bearing the words "This is sold as a mixture of chicory and coffee."

(c.) Where the admixture of chicory exceeds 75 per cent., that the seller delivered with or on such mixture a notice by a label distinctly and legibly written or printed stating the proportion of chicory contained in such mixture.

5. This Act shall be read and construed with the Sale of Food and Drugs Act, 1875, and any Act amending the same.

6. This Act may be cited for any purposes as the Sale of Food and Drugs Act (1875) Amendment Act, 1892.

	1891.	1892.
Metals.....	£ 2,072,814	£ 1,837,214
Chemicals and dyestuffs.....	843,379	783,674
Oils.....	181,971	608,108
Raw materials for non-textile industries.....	3,129,869	2,912,160
Total value of all imports....	38,002,337	34,920,272

SUMMARY OF EXPORTS.

	Month ending 30th April	
	1891.	1892.
Metals (other than machinery)	£ 3,663,725	£ 3,179,216
Chemicals and medicines	800,492	677,211
Miscellaneous articles.....	3,091,150	2,367,571
Total value of all exports.....	20,919,066	17,865,876

IMPORTS OF METALS FOR MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Copper:—			£	£
Ore..... Tons	5,579	11,394	44,780	82,478
Regulus..... "	16,625	11,562	405,983	294,529
Unwrought "	3,323	2,329	183,268	199,842
Iron:—				
Ore..... "	265,659	311,713	215,138	230,810
Bolt, bar, &c. ... "	3,119	3,446	28,846	28,058
teel, unwrought.. "	514	352	6,519	3,596
Lead, pig and sheet ..	12,995	18,454	161,621	293,376
Pyrites..... "	55,648	62,691	105,781	199,986
Quicksilver..... Lb.	538,425	137,435	58,759	12,260
Tin..... Cwt.	62,806	46,948	281,912	213,097
Zinc..... Tons	4,830	3,424	110,709	79,081
Other articles... Value £	469,498	470,101
Total value of metals	2,072,814	1,837,214

IMPORTS OF RAW MATERIALS FOR NON-TEXTILE INDUSTRIES FOR MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Bark, Peruvian .. Cwt.	9,820	9,075	£ 23,195	£ 21,613
Bristles..... Lb.	260,837	144,703	43,758	21,753
Caoutchouc..... Cwt.	29,563	20,915	406,470	203,159
Gum:—				
Arabic..... "	4,738	4,036	13,156	12,830
Lac, &c..... "	15,867	19,370	61,114	75,204
Gutta-percha "	6,138	5,844	64,236	79,847
Hides, raw:—				
Dry..... "	48,188	42,904	117,052	110,049
Wet..... "	34,355	38,910	78,341	82,064
Ivory..... "	1,048	1,246	59,027	62,126
Manure:—				
Guano..... Tons	3,660	1,278	17,557	9,111
Bones..... "	10,366	11,042	50,137	50,040
Paraffin..... Cwt.	60,944	43,651	88,185	59,110
Linen rags..... Tons	3,216	3,349	30,919	29,529
Esparto..... "	19,251	16,340	91,544	74,796
Pulp of wood "	12,390	13,344	59,631	69,699
Rosin..... Cwt.	193,553	166,286	26,470	34,314
Tallow and stearin ..	181,172	122,519	224,052	157,406
Tar..... Barrels	2,820	1,275	1,274	799
Wood:—				
Hewn..... Loads	199,443	219,072	340,213	372,004
Sawn..... "	142,007	211,333	326,394	492,112
Staves..... "	8,046	11,734	47,828	66,962
Mahogany..... Tons	4,142	6,883	39,881	62,521
Other articles.... Value £	907,732	804,472
Total value	3,120,869	2,942,160

Besides the above, drugs to the value of 81,277*l.* were imported as against 88,863*l.* in April 1891.

IMPORTS OF CHEMICALS AND DYESTUFFS FOR MONTH
ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Alkali..... Cwt.	7,668	5,503	£ 4,119	£ 2,997
Bark (tanners, &c.) „	41,073	36,071	16,164	17,129
Brimstone..... „	28,189	59,036	9,663	16,089
Chemicals..... Value £	113,787	115,393
Cochineal..... Cwt.	625	363	3,889	2,273
Cutch and gambier Tons	2,417	2,484	56,328	57,032
Dyes:—				
Aniline..... Value £	26,759	11,263
Alizarine..... „	27,254	20,126
Other..... „	739	1,439
Indigo..... Cwt.	4,399	2,287	69,157	39,044
Nitrate of soda.... „	603,719	457,266	267,113	196,826
Nitrate of potash. „	37,659	39,832	32,314	25,894
Valonia..... Tons	1,823	4,356	39,344	61,187
Other articles... Value £	182,809	212,992
Total value of chemicals	843,379	783,674

IMPORTS OF OILS FOR MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Cocoa-nut..... Cwt.	26,092	14,015	£ 39,770	£ 16,397
Olive..... Tons	1,314	1,976	55,298	74,265
Palm..... Cwt.	74,585	111,069	8,5648	120,430
Petroleum..... Gall.	8,224,252	10,493,718	179,668	222,377
Seed..... Tons	1,684	1,972	41,199	48,373
Train, &c..... Tons	576	587	12,798	12,519
Turpentine..... Cwt.	4,445	19,259	5,857	22,922
Other articles... Value £	63,496	80,185
Total value of oils...	181,974	608,168

EXPORTS OF DRUGS AND CHEMICALS FOR MONTH ENDING
30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Alkali..... Cwt.	524,749	662,650	£ 107,862	£ 169,344
Bleaching materials „	119,533	114,588	49,576	45,189
Chemical manures. Tons	24,817	25,006	181,840	159,809
Medicines..... Value £	97,253	85,214
Other articles... „	28,296	217,395
Total value.....	500,492	677,211

EXPORTS OF METALS (OTHER THAN MACHINERY) FOR
MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Brass..... Cwt.	9,091	8,296	£ 43,834	£ 38,254
Copper:—				
Unwrought..... „	73,703	79,662	204,506	194,669
Wrought..... „	30,995	27,007	102,562	80,395
Mixed metal..... „	21,885	26,869	69,786	67,883
Hardware..... Value £	218,055	181,401
Implements..... „	116,536	112,499
Iron and steel..... Tons	287,422	223,518	2,612,179	1,835,715
Lead..... „	4,214	4,973	62,182	61,518
Plated wares... Value £	39,026	21,060
Telegraph wires, &c. „	59,226	447,883
Tin..... Cwt.	9,920	8,594	47,134	40,719
Zinc..... „	17,614	21,742	19,478	29,245
Other articles... Value £	78,211	76,975
Total value.....	3,663,725	3,179,216

EXPORTS OF MISCELLANEOUS ARTICLES FOR MONTH
ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1891.	1892.	1891.	1892.
Gunpowder..... Lb.	1,058,800	622,800	£ 23,974	£ 15,144
Military stores.. Value £	116,926	88,352
Candles..... Lb.	1,357,700	1,422,500	26,433	27,387
Caoutchouc..... Value £	114,575	97,582
Cement..... Tons	62,162	34,978	125,960	66,638
Products of coal Value £	179,689	123,256
Earthenware... „	176,350	151,867
Stoneware..... „	15,844	13,696
Glass:—				
Plate..... Sq. Ft.	240,823	191,468	14,264	11,390
Flint..... Cwt.	9,669	7,446	20,058	16,659
Bottles..... „	81,249	62,559	38,303	29,811
Other kinds.... „	17,331	21,514	13,150	16,575
Leather:—				
Unwrought..... „	11,814	11,818	107,762	112,211
Wrought..... Value £	30,449	21,582
Seed oil..... Tons	8,271	5,906	185,670	117,476
Floorecloth..... Sq. Yds.	1,505,700	1,155,100	65,636	48,380
Painters' materials Val. £	152,245	118,335
Paper..... Cwt.	95,196	79,457	162,731	131,991
Rags..... Tons	3,613	4,606	29,527	31,858
Soap..... Cwt.	15,657	48,359	52,841	52,142
Total value.....	3,091,150	2,367,571

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

7533. J. Duckett, A. Duckett, and H. Stephenson. *See* Class IX.

7753. J. Morrison. Improvements in ejectors for ejecting water, thick or thin, or tar and ammonia water. April 25.

7923. W. Foulis. Improvements in apparatus for regulating the flow and pressure of gas. April 27.

8155. J. Bonnoure. Improvements in distilling apparatus. April 29.

8773. G. F. Redfern.—From W. P. Abell, British Guiana. *See* Class XVI.

9140. A. Koehl. Improved apparatus for evaporating solutions. May 13.

COMPLETE SPECIFICATIONS ACCEPTED.*

1891.

8823. A. McDougall. Covering lead surfaces to protect water and other liquids from contamination with the dissolved metal. May 18.

9187. E. J. Mills and C. J. Ellis. Means and method of closure for the regulation of gaseous pressures. May 18.

9318. A. J. Boulton.—From A. Klönne and P. Bredel. Apparatus for charging retorts. May 11.

10,456. H. L. Callendar. Pressure gauges, suitable especially as piezometers, barometers, thermometers, and the like. April 27.

10,771. W. J. Tranter and S. Hale. Compound for preventing incrustation and corrosion in steam and other hot-water boilers. May 4.

10,833. A. W. Ellis. Stand for chemical or other purposes. May 4.

10,902. J. F. Braidwood. *See* Class II.

11,034. R. Harvey. Evaporating apparatus. May 4.

11,210. L. H. Armour. *See* Class II.

14,221. J. Tobin. New method of applying soda to internal parts of boilers for preventing the formation of scale. May 4.

16,965. R. Morris. Preventing incrustation in steam boilers. April 27.

1892.

5325. H. H. Lake. — From T. Craney. Evaporating apparatus. May 4.

5377. S. H. Johnson and C. C. Hutchinson. Apparatus for mixing liquids with liquids and solids. May 18.

5619. J. A. Fisher. Construction of non-conducting coverings to prevent the radiation of heat. April 27.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

7379. A. J. Boulton.—From H. C. Rew, United States. Improvements in or connected with gas generators. Complete Specification. April 19.

7468. A. Philburn. An improvement in apparatus for burning smoke. April 20.

7614. G. Heslop. *See* Class VII.

7708. J. C. Chaudler. Improvements in apparatus for washing, purifying, and scrubbing gas. April 23.

7709. H. Pazolt. The manufacture of an improved artificial fuel. April 23.

7888. J. H. W. Stringfellow. Improvements relating to the distillation of coal and other substances for gas-making and other purposes, and in apparatus therefor. April 26.

7983. P. Dvorkovitz. Improvements in apparatus for the manufacture of gas for illuminating or heating purposes, applicable also for the distillation of liquid hydrocarbons. Complete Specification. April 27.

7995. J. P. Bayly. An improved apparatus for charging inclined gas-retorts. April 28.

8159. R. Marshall. Improvements in the combustion of fuel and apparatus therefor. Complete Specification. April 30.

8207. W. Hawkins, T. Hawkins, H. Fuller, and W. H. Fuller. An improved metallic block to be used in the production of gas. April 30.

8426. A. Longsdon.—From F. Krupp and Co., Germany. New or improved processes for the manufacture of gas from water vapour, and for purification and separation of mixed gases. Complete Specification. May 4.

8481. J. E. Richardson. Improved means or apparatus for generating ozonised oxygen. May 5.

8592. T. D. C. Leveritt. An improvement in the purification of coal-gas used for the purposes of heating and cooking. May 6.

8664. R. Welford. Improvements relating to fuel. May 7.

8892. H. J. Rogers. An improved apparatus for the manufacture of gas for lighting and heating and for use in gas-engines. May 11.

8906. J. Duggan and W. J. Harley. An improved fire-lighter, also applicable for use as a temporary fire. May 11.

8919. T. J. Barnard. Improvements in the manufacture of fuel, together with the means and combinations in connexion therewith. May 11.

9080. W. D. A. Bost and T. F. Haldane. Improvements in the manufacture of fire-lighters. Complete Specification. May 13.

9114. R. N. Oakman, jun. Improvements in gas-producing plant. Complete Specification. May 13.

9171. T. Charlton. Improvements relating to the more perfect combustion of fuel in furnaces. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

10,902. J. F. Braidwood. Apparatus for charging retorts for the manufacture of gas and for other like purposes. May 11.

11,210. L. H. Armour. Ovens, furnaces, retorts, or other structures used in the making of coke or charcoal, or for distilling or roasting carbonaceous matter, or otherwise subjecting carbonaceous matter to the action of heat. May 11.

11,761. A. O. Jones. Manufacture of artificial fuel, utilising sewage therein. May 4.

12,572. G. E. Stevenson. Apparatus for charging inclined gas retorts. May 4.

1892.

5994. J. Rudd. Apparatus and means for increasing the illuminating power of gas. May 4.

6362. C. Bongourd de Lamarre. Process and apparatus for the manufacture of illuminating gas. May 11.

7079. C. R. Collins. Gas-making apparatus. May 18.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATION.

8462. P. H. Bayle and A. Cambray. An improved process of distillation, heating, and condensation of bituminous schists and any mineral substances which by distillation in closed vessels will yield mineral oils, paraffins, ammoniacal waters, and analogous products, and improved apparatus in connexion therewith. May 4.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

8269. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of dialkylised meta-methoxy, meta-ethoxy, and metabenzyloxy-para-amido benzophenones. May 2.

8270. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of azo-colouring matters derived from paraphenylenediamine. May 2.

8455. J. Y. Johnson.—From F. von Heyden, Germany. Improvements in the manufacture of alpha-oxynvitic acid. May 4.

8456. J. Y. Johnson.—From F. von Heyden, Germany. Improvements in the manufacture of colouring matter from alpha-oxynvitic acid. May 4.

8631. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in the manufacture of triphenylmethane dyestuffs. May 6.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

10,861. H. H. Lake.—From K. Oehler. Manufacture of colouring matters. April 27.

11,016. J. Y. Johnson.—From the Badische Anilin und Soda Fabrik. Manufacture and production of alpha-naphthoquinone dichlorimide, and of basic dyestuffs therefrom. May 11.

11,049. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of meta amidobenzaldehyde, and of salts thereof. May 4.

11,275. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik.—Manufacture and production of new dyes of the rosaniline series and of new materials therefor. May 4.

11,328. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of yellow azo-colouring matters striking on mordants, and absolutely fast against the action of fulling, soap, and light. May 4.

11,472. W. B. Espeut. Manufacture of extracts from logwood and other dyewoods, also in preparing dyewoods for use in dyeing. May 11.

11,629. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture of basic naphthalene colouring matters and of sulpho acids therefor. May 4.

11,663. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Manufacture of colouring matters for dyeing and printing, derived from benzidine and its analogues. May 4.

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATION.

8363. G. Young. Improvements in the process or mode of producing polished, dyed, and bleached yarns or threads, and in machinery or arrangements for the purpose. May 3.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8776. F. V. M. Raabe. Treatment of vegetable textile fibres for the manufacture of yarns and fabrics. April 27.

10,543. W. R. Comings. Impregnating paper and other fibrous materials. April 27.

1892.

5297. P. Temming. A new fabric suitable as a substitute for cotton waste for cleaning parts of machinery, and process for making the same. April 27.

6550. B. J. B. Mills.—From G. Bergier. Spinning and treatment of silk in the manufacture of various classes of silk thread. May 11.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

7440. T. Dawson and H. F. Clayton. Improvements in the method of and apparatus for dyeing cotton and other like textile fabrics. April 20.

7555. C. Schmürch. Improvements in apparatus for effecting the oxidation of aniline black in the process of dyeing cotton thread or wool on bobbins and cops. Complete Specification. April 21.

7628. G. Young and W. Crippin. Improvements in or applicable to mechanism or apparatus for dyeing, bleaching, and otherwise treating cotton and other fibrous materials in the raw or manufactured or partly manufactured state. April 22.

8170. J. Aldred. Improvements in bleaching cotton piece-goods. April 30.

8244. E. Sykes and D. Sykes. Improvements in machinery for scouring and dyeing hanks of yarn. May 2.

8364. M. Löb. Improvements connected with the dyeing of stockinette. May 3.

8921. T. T. Whittington. "Whittington's" direct mordant for dyeing cotton and linen fabrics. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9470. R. Landam and D. Gulland. Method and apparatus for embossing, colouring, and printing upon paper or other suitable material. May 18.

10,138. E. B. Truman. Solution for use in the dyeing of silk fabrics, yarns, and threads. May 11.

10,678. E. Sutcliffe and G. E. Sutcliffe. Dyeing and treatment of cotton and other textile materials. May 18.

11,327. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Process of dyeing silk a solid black by means of alizarine, flavopurpurine, anthrapurpurine, and mixtures of these bodies. May 4.

20,737. C. H. Nevill. Process for producing designs upon calico and other woven fabrics. May 28.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

7393. F. Hurter. Improvements in the manufacture of bleaching powder and apparatus to be employed therein. April 19.

7528. J. W. Smith and H. B. Jagger. Improvements in the manufacture of vinegar. April 21.

7614. G. Heslop. The application of a by-product of the manufacture of acetates for warming and heating purposes. April 22.

7958. H. Precht. A process for the production of phosphates of potassium or aluminium soluble in water. April 27.

7997. H. C. Bull. Improvements in or connected with the manufacture of ferric chloride. April 28.

8276. La Société A. R. Pechiney and Cie. Improvements in means or apparatus for the manufacture of a mixture of hydrochloric acid gas and air. Filed May 2. Date applied for November 28, 1891, being date of application in France.

8890. B. E. R. Newlands. Improvements in the purification of carbonic acid. May 11.

8964. W. P. Thompson.—From W. B. Brittingham, United States. New or improved bleaching compound. Complete Specification. May 11.

9181. J. Hargreaves and J. Hargreaves. Improvements in apparatus employed in the manufacture of sulphate of soda. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9732. D. Rylands. Manufacture of carbonic acid gas, and in tubes for containing the same. May 18.

9947. A. T. Hall. Treatment of waste liquors from metallurgical processes to obtain sulphurous or sulphuric acid and zinc. May 4.

9948. A. T. Hall. Treatment of waste liquors from metallurgical processes to obtain sulphurous or sulphuric acid and oxide of iron. May 4.

10,630. A. Dupré.—From F. Dupré. Manufacture of potassium carbonate. April 27.

11,469. T. H. Bell.—From T. Schloesing. Manufacture of anhydrous chloride of magnesium, and the apparatus used therein. May 11.

11,470. T. H. Bell.—From T. Schloesing. Manufacture of chlorine, and apparatus used therein. May 11.

1892.

5425. J. C. Ody. Method for making caustic soda (sodium hydrate). April 27.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

7792. C. F. E. Grosse. An improved method of producing marbled glass. Complete Specification. April 25.

7906. H. C. Bull. Improvements in or connected with casting tables for glass and glass making. Complete Specification. April 27.

8361. J. Rigby. To make pressed plate glass of any thickness or any colour or design. May 3.

8517. H. W. Cox. Improvements in vitrifying photographic prints on glass, metal, porcelain, china, and like substances. May 5.

8865. V. B. Lewes. Improvements in the manufacture of glass. May 10.

8896. T. H. Hunt. Improvements in appliances employed in the glazing of earthenware pipes and analogous articles. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

10,454. J. Armstrong. Manufacture of tanks or boxes and other articles of glass, and mechanism or appliances to be used in the said manufacture. April 27.

10,817. I. Pennell and J. T. Harris. Apparatus or appliance for use in supporting ceramic ware in enamel kilns whilst being fired. May 4.

11,039. P. Sievert. Process for producing glass articles with metal enclosures. May 4.

11,205. H. J. Chappell. Machines for pressing and moulding plastic materials. May 11.

16,005. G. Pitt. Mode of constructing flues for brick, terra-cotta, and other kilns. May 4.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

7490. G. Martenstein. Improvements in the manufacture of materials for street and other pavements. April 20.

7502. W. P. Thompson.—From L. O. Roeser-Müller and B. Deike, Germany. Improvements in and in the manufacture of plaster for building purposes. Complete Specification. April 20.

7533. J. Duckett, A. Duckett, and H. Stephenson. Improvements in and relating to the construction of kilns or ovens for drying and burning bricks, tiles, lime, and the like. April 21.

7719. S. Théraizal and F. Grand'Montagne. Improvements in the manufacture of artificial marble. April 23.

7744. J. C. Bloomfield. Improvements in the manufacture of plaster. April 25.

7850. E. T. Warner and J. F. Curry. An improvement in the art of making mortar. Complete Specification. April 26.

7857. A. Angell and F. Candy. Improvements in the manufacture of hydraulic cement from sewage sludge. April 26.

8232. G. M. Graham. Improvements in artificial stone blocks. Complete Specification. May 3.

8460. W. W. Hewitt and A. Stuart. Improved compounds for paving or covering roads, paths, or floors, and for manufacture of paving bricks or blocks. May 4.

8777. T. W. Brittain. Improvements in apparatus for grinding cement or other substances. May 9.

8889. F. H. Willis and R. Astley. An improved form and method of constructing fireproof floors and stairs. May 11.

9209. R. Astley. An improved form and method of construction of fireproof floors. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

7845. H. Faija. Continuous or running kilns for the calcination of cement. May 11.

11,209. H. Aitken. Treatment of stone, brickwork, plaster, or stucco, and the like, for preventing deterioration thereof. May 18.

12,730. F. Wachsmuth. Process for use in the manufacture of gypsum objects. May 11.

16,005. G. Pitt. See Class VIII.

21,199. R. Norwood. The manufacture of an improved compound for coating walls and other surfaces, and for the production of casts or mouldings, and for analogous purposes. May 4.

21,374. R. Norwood. The manufacture of an improved compound for coating walls and other surfaces, and for analogous purposes. May 18.

1892.

5746. A. T. Morse. Distemper for walls, ceilings, and the like. April 27.

6745. V. F. L. Smidth. Manufacture of hydraulic cement for building purposes. May 18.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

7378. P. C. Choate. Improvements in the art of producing metallic zinc. Complete Specification. April 19.

7418. W. Mayer. The manufacturing of cast iron expansive moulds used for molten materials of different kinds. April 20.

7473. C. H. Aston. Improved methods of utilising slag made in connexion with iron and steel furnaces. April 20.

7748. R. Evans and E. Davies. Improvements in means or apparatus to facilitate the manufacture of moulds for use in casting moulds for ingots of steel or other metal. April 25.

7758. H. Höfer. Improvements in refining iron. April 25.

7795. J. Colley and A. Colley. Improvements in the manufacture of steel and iron. April 26.

7832. H. A. Penrose. Improvements in or relating to the treatment of silver ores containing zinc and gold ores containing zinc. April 26.

7909. G. Wegner. A process for galvanising aluminium. Complete Specification. April 27.

8121. A. Brin. Improvements in converting and refining metals, and in cupolas or apparatus employed therein. April 29.

8257. C. M. Pielsticker. Improvements in the method of extracting gold and silver from ores. May 2.

8280. E. Bonehill. Improvements in the manufacture of iron, and in apparatus therefor. May 2.

8393. W. Holland. Improvements in apparatus or means for hardening and tempering metals. May 4.

8400. H. J. Smith. Improvements in the manufacture of pig-iron or steel ingots. May 4.

8467. H. R. Lewis and C. Gelstharp. Improvements relating to the treatment of ores containing blende or zinc in association with gold, silver, lead, copper, antimony, sulphur, and other metals or metalloids, and to apparatus therefor. May 4.

8523. J. Simpson. Improvements in the separation of gold or silver from auriferous or argentiferous sulphide of antimony ores, sometimes called stibnite. May 5.

8551. A. J. Boulton.—From C. Sauer, Germany. Improvements in or relating to aluminium solder. May 5.

8571. J. J. Lish. Improvements in the treatment of blast-furnace slag. May 5.

8612. E. H. Sumter. Improvements in or relating to the purification of iron or steel therefrom. Filed May 6. Date applied for January 21, 1892, being date of application in Belgium.

8779. J. B. Chamberlain and A. Gutensohn. An improved process for the preparation of iron or steel plates to receive electro-plating of other metals, such as silver, gold, or nickel. May 9.

8834. E. W. Cooke. An alloy. Complete Specification. May 10.

8861. C. F. Hengst. An improved metallic alloy. May 10.

8887. T. Twynam. Improvements in the utilisation of tin plate, scrap, and tin slags and residues. May 11.

8932. W. H. Luther. Improvements in and relating to baths for coating metallic plates. May 11.

9098. A. Needham. Improvements in the manufacture of steel, iron, or other material to be used in the making of treads for stairs, steps, and floors. May 13.

9127. J. Y. Johnson.—From N. Lébédoff, Russia. Improvements in the extraction of metals from ores or metalliferous materials. May 13.

9128. J. Y. Johnson.—From N. Lébédoff, Russia. Improvements in the manufacture of alloys of aluminium. May 13.

9146. W. A. Briggs. An improved alloy of aluminium. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

2361. J. B. Alzugary. Improvements in metal alloys. May 18.

8819. W. Bevan. An annealing apparatus to be applied to heating furnaces for iron, steel, or metal sheets and plates. April 27.

8837. The Rovello Syndicate, Lim., and J. C. Howell. Apparatus for use in obtaining copper. May 4.

9117. J. O. Day. Alloys and compositions for use in covering and coating surfaces of iron and steel, and the surfaces of other materials, in order to prevent corrosion and fouling thereof when submerged. April 27.

9708. C. J. Fauvel. Furnace for the treatment of refractory ores. May 4.

10,761. C. W. Bildt, G. Ashworth, and E. Ashworth. Linings for Bessemer converters. May 4.

10,984. F. H. Mason. Process for the extraction of tin from tin slags or tin refuse by founders' ashes, copper salts, carbonaceous matter, fluorspar, and other suitable fluxes. May 18.

11,095. J. S. Taylor and S. W. Challen. Process or method of manufacturing metal tubes. May 4.

11,190. F. W. Harbord and W. Hutchinson, jun. The utilisation of tin-plate scrap. May 11.

11,208. J. Turton. Process for the extraction of metals from ores and metal minerals containing them. May 4.

11,247. L. Reuleaux. Construction and working of smelting and melting furnaces. May 11.

1892.

4173. P. Rossigneux. Method and means of desulphurising castings or alloys of certain metals. May 4.

6038. G. Wegner. Solder for joining together aluminium pieces or pieces of aluminium with other metals. May 4.

6704. S. H. Brown. Compound for carburising metals. May 18.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

7412. Sir C. S. Forbes, Bart. An improved battery element. April 19.

8083. J. O. Dale. A means of electrically heating iron, steel, and other metals in the processes of rolling, drawing, pressing, and stamping. April 29.

8108. J. W. Davis and J. O. Evans. Improvements in the manufacture of metallic articles by electro-deposition. April 29.

8529. W. Moseley. Improvements in galvanic batteries. May 5.

8572. H. Beckmann, E. Beckmann, and J. Schmitt. An improved galvanic element. Complete Specification. May 5.

8987. P. Germain. Improvements in secondary batteries and accumulators. Filed May 12. Date applied for February 23, 1892, being date of application in France.

9014. H. J. Allison.—From P. Kennedy and C. J. Diss, United States. Improvements in storage batteries. May 12.

9132. H. Howard. Improvements in heating and welding by electricity. May 13.

9192. A. J. Boulton.—From F. C. Bromley. Improvements in the electrolysis of chloride and other solutions. Complete Specification. May 14.

9197. A. J. Boulton.—From E. Liebert, Belgium. A process of extracting zinc, iron, lead and copper from the solutions of their salts by electrolysis. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9652. A. Watt. Production of copper tubes by electrolysis. March 18.

11,060. P. Giraud. Thermo-electro batteries. May 4.

11,560. G. G. M. Hardingham.—From J. H. Hard and H. Coumett. Galvanic batteries. May 11.

18,997. C. N. Souther. Galvanic batteries. May 11.

19,617. M. Muthel. Exciting fluid for galvanic zinc carbon batteries, and method of recovering useful products from the spent fluids of such batteries. April 27.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

7354. R. Bell. Improvements in the manufacture of soap. April 19.

7581. R. Stewart. Improvements in soap or washing-powder. Complete Specification. April 21.

8217. C. Kloeble. An improved soap tablet. April 30.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

10,516. R. J. Jordan. Compound for cleansing purposes. May 11.

11,799. N. M. Henderson. Treating or purifying paraffin wax, and apparatus therefor. May 18.

11,889. O. C. Hagemann.—From E. K. Mitting. Treatment and purification of soap-makers' spent lye for extracting glycerin therefrom. May 18.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

7353. R. Bell. A new or improved compound or mixture for preventing the fouling of ships' bottoms and other submerged surfaces or structures. April 19.

7631. E. Waller and C. A. Sniffen. Improvements in the manufacture of white lead for use as a pigment. April 22.

7688. W. Cutler. Improvements in the manufacture of gold, silver, and bronze paints. April 23.

8199. B. Goldmann. Improved dryer for paints and the like. April 30.

8765. J. Burbridge. Improved mode of preparing variegated rubber for manufacturing purposes. May 9.

9135. F. D. Mott. An elastic or resilient covering for ships' bottoms. Complete Specification. May 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8480. F. Ragon. Manufacture of material applicable as a blacking and for other purposes. April 27.

1892.

5287. J. W. H. James. Manufacture of white lead, and apparatus therefor. May 4.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

7698. A. J. Boulton.—From A. E. Ebert, Germany. Improved manufacture of substitute for leather. Complete Specification. April 23.

8469. H. H. Lake.—From Durio Bros., Italy. Improvements in and relating to tanning hides and skins. Complete Specification. May 1.

COMPLETE SPECIFICATIONS ACCEPTED.

1892.

6416. W. P. Thompson.—From F. A. Wolff. Apparatus for the treatment of liquid gelatin or glue for the ultimate production of plates or sheets of such. May 11.

XV.—AGRICULTURE AND MANURES.

APPLICATIONS.

8859. T. M. Smith. Improvements in and in the method of manufacture of fertilisers. Complete Specification. May 10.

8901. J. S. Yule. An improved manurial compound obtained in filtering sewage. May 11.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

8274. A. Walker. Improvements in the treatment and saccharification of grain and other materials containing starch, dextrin, or similar substances. May 2.

8336. W. P. Thompson.—From J. A. Morrell and W. R. Stringfellow, United States. New or improved process and apparatus for concreting sugar, or crystallising saline or other solutions. Complete Specification. May 3.

8773. G. F. Redfern.—From W. P. Abell, British Guiana. Improvements relating to filtering apparatus for saccharine and other liquors. May 9.

9167. S. C. B. Hunter. A new or improved treacle or syrup compound. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

11,874. R. Harvey. Manufacture of sugar, and apparatus therefor or connected therewith. May 18.

1892.

6160. R. Brockhoff. Apparatus for manufacturing sugar. May 4.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

7534. J. Y. Johnson.—From J. A. Saladin, France. Improvements in the manufacture of malt and in the apparatus employed therein. April 21.

7547. O. Ritter, J. H. A. Meyer, and L. Hofman. An improved wort and yeast aerator. April 21.

7643. A. H. Hobson. Improvements in the production of non-alcoholic ales or beers. April 22.

8060. J. Chesmore. A new or improved non-alcoholic ale. April 28.

8290. H. Gehrke. Improvements in apparatus for filtering beer and other alcoholic and gaseous liquids. Complete Specification. May 2.

8623. T. Haynes, jun. An improvement in the drying and curing of malt. May 6.

8952. P. M. Justice.—From A. W. Billings, United States. Improvements in apparatus for the manufacture of malt liquors. Complete Specification. May 11.

9165. R. G. Ross, J. B. Hilliard, and W. Paterson. A new or improved method of purifying and hardening water for use in the manufacture of malt extract, and for brewing and analogous purposes. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

11,123. M. A. Adams and C. S. Meacham. New or improved means for the preservation of hops. May 4.

1892.

4682. A. J. Boulton.—From The Pfandler Vacuum Fermentation Co. Manufacture of beer. April 27.

4688. A. J. Boulton.—From the Pfandler Vacuum Fermentation Co. Manufacture of beer. April 27.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

7789. E. Edwards.—From F. Grognet, France. An improved process and apparatus for preserving meat, fish, and other perishable substances. April 25.

7848. E. Barker. Improvements in or relating to the preparation or treatment of certain waste products to make them suitable for use as food and in apparatus therefor. April 26.

8264. G. Müller. Process of producing sterilised butter. Complete Specification. May 2.

8727. A. P. Wire. Improvements in the preservation of animal and vegetable substances. May 9.

B.—Sanitary Chemistry.

7721. H. H. Hazard. A system for the treatment of smoke, gases, fumes, or chemical products arising from any furnace, chimney, vent, fire-place, or outlet, so as to prevent the contamination of the atmosphere and the evils arising therefrom, and for making use of the products. April 23.

C.—Disinfectants.

8725. C. F. Hiron. The Hiron's disinfectant and air purifier. May 9.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1892.

5589. S. L. West. Apparatus for purifying, sterilising, and filtering water, and rendering the same fit for potable purposes. April 27.

5725. J. Faleimagne. Preservation of meat and fatty matters. April 27.

6841. W. Crawford. Manufacture of malt bread, biscuits, confectionery, and other articles of diet. May 18.

B.—Sanitary Chemistry.

1891.

10,929. W. E. Adeacy. Treatment of sewage sludge. May 4.

11,761. A. O. Jones. *See Class H.*

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

8239. W. Saunders. Highly everlasting solid white non-fading opaline key covering for pianofortes, organs, &c. May 2.

8473. J. Robertson. Improvements in the manufacture of vegetable parchment. May 4.

8700. C. F. Cross, E. J. Bevan, and C. Beadle. Improvements in dissolving cellulose and allied compounds. May 7.

8713. S. G. Rawson. Improvements in and in the manufacture of waterproof paper, cardboard, and the like. May 7.

8810. K. L. Grubert. An improved method of manufacturing variegated plates of wood-pulp or cellulose, and other plastic materials. May 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

8487. A. Sheldon. Apparatus for the manufacture of paper pulp. May 18.

10,513. W. R. Comings. *See Class V.*

1892.

433. H. Richardson and H. Glenny. Manufacture of paper, and apparatus used for that purpose. May 11.

2629. V. B. Drewsen. Method of purifying the liquid which has been used in the manufacture of cellulose, and the production of useful products therefrom. April 27.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

7782. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of periodides of phenols and phenolcarboxylic acids. April 25.

7979. E. Kauder and L. Merck. Improvements relating to the production of narceinesodium-sodium-salicylicum. April 27.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

11,833. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co.—Manufacture and production pharmaceutical compounds. May 11.

11,844. J. F. von Mering. Improved anæsthetic and hypnotic. May 11.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

7414. E. Hooker. Improved means and ingredients for colouring and tinting photographic silver prints. April 19.

7501. A. J. Boulton.—From G. Eastman, United States. Improvements in or relating to photographic films or the like. April 20.

7567. T. Christy. Improvements in the manufacture of transparent materials and the application of the same to photographic and other purposes. April 21.

8145. C. E. Elliott. Improvements in connexion with artificial-light photography. Complete Specification. April 29.

8328. E. H. Fitch. Improvements in and connected with photographic sensitised celluloid films. May 3.

8967. A. J. Boulton.—From G. Eastman, United States. Improvements in or relating to photographic plates or films. May 11.

COMPLETE SPECIFICATION ACCEPTED.

1891.

10,101. J. Joly. Methods of obtaining solar altitudes by the aid of instantaneous photography. May 11.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

7392. A. R. Molison and A. McLucas. A steam cartridge for blasting purposes. April 19.

7978. C. H. Curtis and G. G. André. Improvements in explosives. April 27.

7981. J. Lawrence. Improvements relating to the extraction of nitro-glycerin from the waste acid formed in the manufacture of nitro-glycerin. Complete Specification. April 27.

8256. G. W. Thomas. Improvements in matches, fusees, and the like. May 2.

8740. M. Mullineux. Improvements in smokeless cartridges. May 9.

8926. C. O. Lundholm and J. Sayers. Improvements in the manufacture of explosives. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

9485. T. Holmes. Safety-fuse igniting to be used in conducting blasting operations in mines, quarries, and the like. May 18.

14,429. G. C. Dymond.—From E. Lagneau. Manufacture of matches, and apparatus or machinery therefor. May 11.

19,346. P. W. Masson. Time or distance fuse for explosive shells. May 11.

THE JOURNAL

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 6.—Vol. XI.]

JUNE 30, 1892.

[Non-Members 30/- per annum; Members 21/- per Set of extra or back numbers Single Copies (Members only) 2/6.]

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, K.C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.

COUNCIL FOR YEAR ENDING JULY, 1892.

President: Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.

Vice-Presidents:

Sir Lowthian Bell, Bart., F.R.S.	<i>Ludwig Mond, F.R.S.</i>
Wm. Crowder.	<i>Dr. Hugo Muller, F.R.S.</i>
<i>James Duncan.</i>	B. E. R. Newlands.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Sir John Evans, K.C.B., F.R.S., has been nominated to the office of President; and Professor J. Emerson Reynolds, F.R.S., has been nominated Vice-President under Rule 11.

Dr. F. Hurter, Dr. W. H. Perkin, F.R.S., Mr. John Spiller, and Professor T. E. Thorpe, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. Thos. Tyrer has been nominated an Ordinary Member of Council under Rule 17, in the place of Mr. John Spiller, nominated a Vice-President.

Mr. Ludwig Mond, F.R.S., has been nominated Foreign Secretary; and the Treasurer has been nominated for re-election.

Mr. R. Forbes Carpenter, Mr. C. C. Hutchinson, Mr. John Pattinson, Mr. A. Gordon Salamon, and Mr. E. C. Cortis Stanford have been nominated, under Rule 18, to fill five vacancies among the Ordinary Members of Council.

A ballot list is enclosed herewith.

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in London on the 20th, 21st, and 22nd July next. The following is a synopsis of the arrangements:—

Wednesday, July 20th.

- | | |
|--|-----------|
| 1. Annual Meeting (Drapers' Hall) | 3 p.m. |
| 2. Reception by the President at Galleries of
Royal Institute of Painters in Water
Colours | 8.30 p.m. |
| 3. Smoking Concert at do. do. | 9 p.m. |

Thursday, July 21st.

- | | |
|--|-----------|
| 1. Excursion to Works on the Thames below
Bridge; steamer leaves Charing Cross Pier | 9.30 a.m. |
| 3. The Dinner at "The Ship," Greenwich | 6.30 p.m. |

Friday, July 22nd.

- | | |
|---|-----------|
| Excursion to Windsor and Clevedon; train
leaves Paddington | 9.30 a.m. |
|---|-----------|

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is prepared to offer 5s. apiece for copies of the Society's Journals for January 1883 in saleable condition.

LIST OF MEMBERS ELECTED, 23rd JUNE 1892.

Barden, Alf., Far Bank, Shelley, near Huddersfield, glue and size manufacturer.

Bell, Percy Carter, Fyde Terrace, Fleetwood, Lancashire, analytical chemist.

Buchanan, D. G., Mount Vernon House, Glasgow, analytical chemist.

Duxbury, Thos., Gas Works, Darwen, Lancashire, gas engineer.

Feld, Walther, Chemische Fabrik, Hönningen a/Rhein, Germany, manufacturing chemist.

Ferguson, W. B., 3, Plowden Buildings, Temple, E.C., and Bankfield, Prestwich, barrister-at-law.

Hampson, Jas., 42, Woodland Street, Cheetham Hill, Manchester, chemist.

Harrison, M. C. C., Haverbrack, Bishop Stortford, Essex, brewer.

Holton, E. C., Sherwin-Williams Co., 130, Canal Street, Cleveland, Ohio, U.S.A., chemist.

Howard, Alf., 4, Prince's Road, Lewisham, S.E., architect and surveyor.

Hunter, Sidney H., 202, Bow Road, E., mechanical engineer.

Innes, Robt., 85, Brook Road, Bootle, Liverpool, soap works chemist.

Lambert, Alan, 1, Prince's Mansions, Victoria Street, S.W., oil mills director.

McVie, Jas. P., Tennant's Works, Hebburn-on-Tyne, analytical chemist.

Meacham, C. S., Brewery House, Earl Street, Maidstone, Kent, brewer.

Mereer, C. A., Dagmar Lodge, Cheam Road, Sutton, Surrey, chemical apparatus manufacturer.

Russell, W., Summerlee Ironworks, Coatbridge, N.B., analytical chemist.

Slater, Sydney H., 126, Highbury New Park, N., chemical student.

Stein, Sigmund, 323, Vauxhall Road, Liverpool, sugar refinery manager.

Stephens, H. O'Reilly, 20, Brunswick Gardens, Kensington, W., ink manufacturer.

Stewart, Ebenezer, Oilseed Mills, Rochester, Kent, seed crusher.

Turnbull, Saml. G., 10, Rue de Bas Trevois, Troyes (Aube), France, dyer and finisher.

Valentine, A. H., 11, Tenerife Street, Broughton, Manchester, chemist.

Whitney, Willis R., Mass. Inst. of Technology, Boston Mass., U.S.A., assistant in general chemistry.

Wirtz, Dr. Quirin, 28, Great Ormond Street, W.C., consulting chemist.

CHANGES OF ADDRESS.

Allibon, G. H., 1/o Liverpool; c/o Richardson Bros. and Co., 30, Donegall Place, Belfast.

Bailey, C. M., 1/o Uphall; 6, Pampherton, Midealder, N.B.

Barrow, J., 35 (not 65), Bromboro' Road, Bebington, near Birkenhead.

Bayley, Thos., 1/o Merrion; 2, Sandymount Avenue, Ballsbridge, Dublin.

Blythe, Herbert F., 1/o Leyland Road; Southport, Lancashire.

Burdekin, G., Journals to Sutton Lodge Works, St. Helens.

Chorley, J. C., 1/o Warrington; University College, Gower Street, W.C.

Christie, John, Journals to Levenfield, Alexandria, N.B.

Coomber, Thos., 1/o Clifton; 40, Clarendon Road, Redland, Bristol.

Cunningham, H. D., 1/o Hebburn; 14, Griffin Street, York Road, S.E.

Curphey, W. S., 1/o Strathbungo; 15, Bute Mansions, Hillhead, Glasgow.

"Engineer, The," 1/o Strand; 33, Norfolk Street, Strand, W.C.

Everett, H. B., 1/o Borneo; Highclere, Marlborough Road, Tooting, S.W.

Fleck, H., 1/o Tübingen; 108, Rittenhouse Street, Germantown, Philadelphia, Pa., U.S.A.

Francis, E. G., 1/o Halstead Villas; c/o Manbré Saccharine Company, Hammersmith, W.

Gilmour, J. D., 1/o 138; 142, Aitkenhead Road, South Side, Glasgow.

Graham, J. A., 1/o Dunmow; The Rookery, Dovercourt.

Harvey, E. Feild, 1/o Brompton; c/o C. W. and W. Gray, 31, Great St. Helens, E.C.

Holland, Philip, 1/o Albert Road; c/o Jas. Greenway, 33, London Street, Southport.

Houston, R. S., 1/o Hope Villa; Brisbane House, Bellahouston, Glasgow.

Kemp, W. J., 1/o Croydon; Mountfield, Hawkhurst, Kent.

King, Walter R., 1/o St. John's Road; 1, Florence Villas, Haulleigh Road, Southend.

Knaggs, A. Batty, 1/o Leeds; Springfield Mill, Morley, near Leeds.

Krause, O. H., 1/o box 577; Box L., Jersey City, N.J., U.S.A.

Latham, B., Journals to 13, Victoria Street, Westminster, S.W.

Lenox, L. R., 1/o Washington; Stanford University, Palo Alto, Cal., U.S.A.

Limpach, Dr. L., 1/o Manchester; Schweinfurt, Germany.

Miller, Robt., 1/o Manchester; 79, West Nile Street, Glasgow.

Moore, Thos., 1/o Thio; "Le Nickel," Noumea, New Caledonia.

O'Neill, Charles, 1/o Carter Street; 14, Cecil Street, Greenheys, Manchester.

Pitt, Theo, 16 (not 12), Coleman Street, E.C.

Roberts, C. F., 1/o Bradford; Linfitts, Delph, via Oldham.

Sharp, Henry, 1/o Bournemouth; Sutherland House, Southampton.

Small, J. I., Journals to Harcourt, Bickley, Kent.

Smith, Fred., 1/o Box 1812; c/o W. J. Kent, Box 291, Johannesburg, S.A.R.

Takamine, J., 1/o Japan; 907, Chamber of Commerce Building, Chicago, Ill., U.S.A.

Walton, F., 1/o Portugal Street; 114, Holborn, E.C.

Williams, Percy B., 1/o The Bank; 22, Bisham Gardens, Highgate, N.

CHANGES OF ADDRESS REQUIRED.

Gibson, Dr. J., 1/o 15, Dick Place, Edinburgh.

Venables, T., 1/o 3, Gardner Street, Glasgow.

Deaths.

Ellis, G. E. R., at Nelson, British Columbia.

Fullarton, R., 30, Donegall Place, Belfast.

Pringle, Wm., Castle Street, Bangalore, India.

Sieher, C. H., Whitworth, near Rochdale.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: T. Tyrer.

Vice-Chairman: W. Crowder.

Committee:

C. F. Cross.

J. Dewar.

A. G. Green.

S. Hall.

C. W. Heaton.

D. Howard.

W. Kellner.

W. Ramsay.

B. Redwood.

W. S. Squire.

G. N. Stoker.

F. Navier Sutton.

Wm. Thorp.

T. E. Thorpe.

Hon. Local Secretary: John Heron.

Ellerdaie, Cottenham Park, Wimbledon.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman:* Wm. Thorp. *Secretary:* John Heron. *Committee:* C. C. Hutchinson, B. E. R. Newlands, F. G. Adair Roberts, A. Gordon Salaman, T. Tyrer, and Frank Wilson.

SESSION 1891-92.

1892:—

July 20th, 21st, and 22nd—Annual General Meeting

Meeting held Monday, 30th May 1892.

MR. THOS. TYRER IN THE CHAIR.

THE LATE PROF. A. W. VON HOFMANN, F.R.S.

THE CHAIRMAN, referring to the recent death of Dr. Hofmann said, that as a considerable number of industrial chemists in the London Section of the Society were students of his in the days when he occupied the position of Professor of Chemistry in the Royal School of Mines, it was only fitting that at the commencement of the proceedings that evening some reference should be made to the great master. He had, therefore, taken upon himself to communicate with some of those who were most intimate with Dr. Hofmann; among them were Sir Frederick Abel and Dr. Perkin. Sir Frederick Abel was prevented, in consequence of his engagements, which pressed upon him very severely, from attending the meeting, but he had written a letter which would be read; after which he would ask Dr. Perkin to speak of Dr. Hofmann as he knew him, and to move a resolution which Mr. David Howard, Mr. Mond, and Mr. William Thorp would support. Mr. John Spiller, who was away from home, had telegraphed his inability to come, and his sympathy with the action taken. Sir Frederick Abel had written as follows:—"I very much regret that it is impossible for me to attend the meeting on Monday evening, as I could much have wished to have the privilege of moving a resolution expressing the Society's sense of the great loss which chemists have sustained in the death of Hofmann, and the reverential affection with which his memory is cherished by his old pupils, of whom I was the first entered at the college, and from whom I was the first whom he selected as assistant." He would now call upon Dr. W. H. Perkin to pay his tribute of honour to the great master.

Dr. W. H. PERKIN regretted that Sir Frederick Abel could not be present, but he was glad to take the opportunity of saying a few words about the great chemist who

had just passed away, being one of his old pupils, who felt how much he owed from having studied under such a teacher, whose enthusiasm and zeal could not but stimulate any student who had in him a spark of love for his science. His knowledge of Dr. A. W. von Hofmann dated from the year 1853, when he was Professor at the Royal College of Chemistry in Oxford Street, an institution rendered famous by the thorough chemists he made of those who studied there, as well as by the brilliant and continuous flow of scientific work which was produced, not only in his own laboratory, but also by his students, whom he inspired with the love of research. No other laboratory in the kingdom was so fruitful as that of the Royal College of Chemistry, and it was a great loss to this country when Dr. Hofmann left London. Of the value of the work which he achieved during his lifetime it was difficult to form an adequate idea, its amount being so great, and he continued it with unremitting zeal throughout his life; in fact his last paper had only just been published. His researches were of special interest to the Society on account of the technical bearing which many of them possessed, showing the practical value of scientific investigation for the advancement of chemical industry, a fact which was now being so well recognised on the Continent, and was becoming more and more appreciated in this country. To Dr. Hofmann's kind and genial nature all who knew him could testify, and any one who had read the three volumes which he wrote in remembrance of his deceased chemical friends could get some idea of his kindness of heart. Of this he might mention an instance in his own experience. When the Fellows of the Chemical Society gave a dinner in his (Dr. Perkin's) honour on the occasion of his being their President, Dr. Hofmann travelled all the way from Berlin in order that he might preside, a practical mark of friendship for his old student, which he would never forget. He little thought that that would be the last time that he would have the pleasure of seeing his old master, as it proved to be. They had indeed lost a great man, one who left behind him an almost unparalleled record of devotion to chemical science. He would conclude by moving the following resolution:—

"We, the members of the London Section of the Society of Chemical Industry, desire to express our deep sympathy with the family of the late revered Professor A. W. von Hofmann. So many of the members owe all their chemical success to Professor von Hofmann's invaluable instruction, that his memory will ever endure amongst us, and as long as chemical industry exists, his historic discoveries will remain the foundations of no small portion of our work."

MR. DAVID HOWARD felt no small honour in being allowed to speak a few words in expression of the deep regard and the profound respect which he felt for the great man who had been taken away. Those who were under him in the old days knew the marvellous power he had, not only of teaching—which was a great gift—but of communicating that wonderful enthusiasm for science, the love of knowledge for its own sake, which he possessed to an extent which none perhaps had ever exceeded. It might be questioned whether it was quite appropriate to speak of his love of pure science to a body of men who were devoting themselves to applied science. He thought, however, that all the great discoveries in that science were grounded upon a love of truth for its own sake. Truth for itself was the first, the use made of it the second, consideration, and therefore, by one of those paradoxes which have a great meaning underlying them, because he studied truth for itself, he was the great founder of applied science.

MR. LUDWIG MOND said that, although he had not been a pupil of Dr. Hofmann, he considered it a privilege to be allowed to say a few words in his memory. The name of August Wilhelm von Hofmann was revered by everyone who called himself a chemist. He had lived long enough to remember the startling effect which his researches had made on the chemical world during the last 30 or 35 years. He had the pleasure of meeting Dr. Hofmann not much more than a year ago. At that time, although grey, he was as full of life as any one in the room, and as cheerful as only a man who had so splendid a career behind him could be, a man whom he should have hoped to meet again, and

whose researches he expected to enrich our science for many a year to come. He had been taken away in the full strength of his mind, and up to the last day had devoted himself, with that enthusiasm for which he was unparalleled, to the science which they all cherished. Whilst addressing an assembly of technical chemists, he felt bound to call attention to Dr. Hofmann's great appreciation of applied chemistry, which was clearly shown in the classical volumes which he had published on the progress of applied chemistry in 1862 and 1873, works containing more information, and having that information better arranged, than any books on the subject which had ever been written.

MR. WM. THOMAS thought that the speakers had proceeded in very appropriate order. He regretted the absence of Sir Frederick Abel, as Dr. Hofmann's first English student, but was glad that Dr. Perkin, at all events one of his earlier students, was present. He felt it a great honour to be asked to speak, seeing that he was not one of Dr. Hofmann's first English pupils, for it was during the time that he was a student at the College of Chemistry that Dr. Hofmann left England to go to Germany. One of the most striking characteristics of Dr. Hofmann was the amount of attention which he gave to his pupils, and perhaps that was the secret of his success. He made it a practice to see all the first year's students every other day; half of them one day, and the other half the next; and all the second, third, and fourth year students he saw every day at least. It was said that a stamped document was not valid unless it had actually touched the substance of the die; and it seemed to him that this personal contact with the teacher was the great secret of Dr. Hofmann's success with his students. It might have been that some of his pupils were very unrecceptive, and did not do him credit; but still he believed that his close attention to them (which, together with the immense amount of work he had on hand in the way of private research and consulting practice, must have meant a large amount of personal self-sacrifice), was the means of giving to his pupils something of that enthusiasm to which Dr. Perkin had referred. Some three or four years ago, happening to be in Berlin, as a matter of course, as an old pupil, he called upon his former teacher. He was received very cordially and they had a long talk about old times. Perhaps one of the things that struck him most was that Hofmann said that although he had then been for twenty years in Germany he thought that he knew London better than he did Berlin, which seemed to imply that his heart was still very much in London. He did not think that a greater loss could be suffered by industrial chemistry than that inflicted by the death of Dr. Hofmann.

THE CHAIRMAN thought that he ought to content himself with putting the resolution as worded; but as one who had been a pupil of Dr. Hofmann at the same time as his friend Mr. David Howard, at a time when Dr. Perkin's researches had become objects of ambition and stimulus for every one of the pupils; when in the same laboratory were Professor Macleod, who was Dr. Hofmann's efficient assistant (where efficiency meant perfection); when Martins, Volhardt, E. J. Mills, Groves, Griess, Valentine, and others well known in applied chemistry were in the laboratory studying in one part of it or another, one felt it an honour to have been in the same place and at work with such men. References had been made to the personal character of Dr. Hofmann, and the enthusiasm which he created in the minds of those who came within the sphere of his influence. There was an atmosphere about the place which was one of industry; a lazy man was told severely and promptly that his room was more valued than his company. The place was small, but it was crowded, and enthusiasm was in the atmosphere. He could say at this distance of time—30 years—that Dr. Hofmann had little reason to be proud of him as a pupil; but he had every reason to thank Dr. Hofmann for having permitted him to study under his influence. The personal influence of Dr. Hofmann had done a great deal more to stimulate enthusiasm than anything else, and it would be a good thing if they could have a Hofmann in every school of science. The science of chemistry had never before had a better professor,

and it seemed hardly possible that they should see his like again. As far as he, personally, was concerned, everything that he was owed to the fact that he had been a pupil of Dr. Hofmann. It had given him his introduction to business; and ever since he had found it a testimony and a passport to favour and to consideration. He confidently asked the meeting to support the resolution.

The resolution was accepted in silence.

VINEGAR MANUFACTURE.

BY J. A. KETTLETON, F.R.S.

IN the works on vinegar-making edited by Braunt, vinegar is defined as consisting of "a dilute solution of acetic acid, contaminated with colouring, flavouring, and extractive matters from various cereals." Whether this definition was the result of his own sad experience, or whether in creating it "the wish was father to the thought" I do not know. Other authors have adopted the same definition. But vinegar, as I prefer to understand it, and as it is manufactured in the United Kingdom, is a fermented and acidified wort derived from malted and unmalted cereals and from sugar. The distillate from such wort may also be included in the definition, as may also the acidified product from the fermented juice of apples, pears, and other fruits. Wine vinegar is another description of the genuine article, and German potato vinegar has some claim to be included also.

I must not attempt this evening to cover the whole course of vinegar making, nor can I even allude to the legal nor to the historical aspects of the manufacture, nor to the older methods of vinegar-making, as they are still conducted in some parts of the country.

On the manufacturing scale the earlier parts of the vinegar-makers routine coincide almost exactly with those of the distiller. He employs any material from which he can economically obtain a saccharine extract, whilst soured ales or wines may occasionally be worked in. As competition with the acetic acid makers is so keen, I will endeavour to show where economies may be effected, and I will therefore refer to three of the most important processes of the manufacture.

Broadly, the object of the vinegar brewer is to obtain from a given weight of grain and sugar materials as much acetic acid as he can, and to obtain it quickly in a palatable and presentable form. To do this it is first necessary to obtain from the same materials the largest possible amount of alcohol, and so, travelling backwards, it will be seen that during the mashing process the extract from the materials should be as high, and the conversion of it to a fermentable form as complete as practical considerations permit of.

With this purpose, and to employ as large a proportion of unmalted material as is possible, it is necessary to ensure the complete gelatinisation of the starchy material and to bring it intimately into contact with—at the best conversion temperatures—the diastatic albuminoids of the malted materials, not neglecting the saccharifying principles possessed by the albuminoids of the unmalted materials. When the mash consists of barley, oats, and wheat, with a proportion of malt, these functions are assisted by first rendering the raw material more friable by kilning it for several hours at a temperature of 110°–120° F. This process assists the mash conversion and doubtless improves the flavour of the final product, not only by driving off the rawness and reducing the bitterness of such materials, but also by its effect during the fermentation process. The kilning may be regarded as practically sterilising the grain, by weakening the mould and bacterial organisms that abound upon it, and so curtailing their effect and reducing their products in the fermenting vat; especially is this the case

if moderate quantities of sulphurous fumes are allowed to play upon the drying grain. Besides this the gain in friability implies a direct gain in extract, gelatinisation is more easily effected, and a more saccharine wort is produced. The system of dry-grist heating prior to mashing, if limited in this manufacture to a temperature of 130° F., will effect most of the same services. When rice and maize grists, whether previously gelatinised or not, are ventured upon, their complete gelatinisation must be secured, either by the acid or the malt conversion treatment, before they are admitted to the malt mash, and this admission must be gradual, so that full play is allowed at or near the optimum diastatic temperature. Even with the ordinary mashes of barley and oats it is better to reserve a portion of the malt grist for mixing with the mash after gelatinisation and cooling to a slightly lower temperature. The same completion of saccharification may be brought about if sufficient of the first and cooler malt extract is held over for admixture in the underback with the final dextrinous runnings from the mash-tun. There are several other ways of manipulating the mash so as to secure the highest extract and one richest in fermentable carbohydrates, besides the obvious one of retaining the final spargings for the next mashing, the principles in each case being, to gelatinise and dissolve the starch, then to cool the wort and bring it into contact with unimpaired diastase. Thus in American distilleries the method is adopted of cold-water mashing, followed by partial draining, then steaming up the grain slowly, and afterwards cooling and finally returning the cold wort first drained off. In any mashing, it is not so much a question of the proportion of malted to unmalted materials, but rather one of how the mixture is made and maintained. The choice of fully-grown but moderately kilned-malt and the utilisation of the powerful diastatic properties of green malt are matters of great importance.

Before leaving the mashing process it may be pointed out that, as the wort is not boiled, a pure water supply is an important consideration. Either by filtration or by heating with moderate quantities of disinfectants, impure supplies should be improved. With the view of slightly encouraging diastatic action during mashing, moderate quantities of those salts which generally appear to effect this result may be added to the mash liquor.

Later on, reference will be made to the use of sugar. Here it is recommended that all sugar worts should be boiled. An obvious advantage of employing sugar is that the mash goods can be thoroughly drained of extract without fear of reducing the gravity too low.

Passing now to the cooling and fermenting operations. If no opportunity exists for aerating the wort during cooling the aeration may be performed in the fermenting back. Not that exhaustive fermentation cannot be guaranteed without any aeration save that resulting from the transitory exposure on the refrigerator, for, as a matter of fact, the attenuation is completed without any additional exposure. But in such cases the fermentation has to be rushed by employing high pitching heats, and allowing the temperature to run up to 94–95° F. during the operation. Excessive quantities of yeast are also added for the same purpose. In several ways these causes are deleterious to the ultimate quality of the wash, besides occasioning a sheer waste of yeast, an item of no little importance when it has to be purchased. Even when yeast production is effected the loss is almost as heavy, for as Adrian Brown has recently shown (*J. Chem. Soc.* 1892, 369) doubling or trebling the quantity of pitching yeast involves neither an increased crop nor in the end an increased alcoholic yield. With much less yeast, a lower temperature, and plenty of aeration, an exhaustive fermentation may be ensured, and as the aeration by modern means, even in the deepest backs, is a simple process, it is to be strongly advocated. Pitching at high temperatures with an excessive quantity of yeast makes it next to impossible to secure a bright wash for admission to the acidifier even if time be allowed for settling and cooling. Again, the system of aeration by means of compressed air forced through a pipe readily permits of the entrance of a much purer quality of air to the wort than the exposure of the wort on a cooler permits of. It may be urged that it is useless to purify such air when it is remembered that the

wort itself has not been boiled, and must, therefore, swarm with disease ferments, and that the acidification process later on necessitates the absorption of a large quantity of aerial impurities. But it must be pointed out that, with a considerably reduced fermentation heat the disease organisms would be less powerful, and their products consequently reduced; and further, that by the judicious use of antiseptics, it is possible still further to limit their action without endangering the main fermentation. As for the impure air entering the draught holes of the acidifier it would doubtless be an improvement if such air were filtered or washed in some way, but even without this it is to be remembered that, during acidification, with increasing quantities of acetic acid and decreasing quantities of nutrient for foreign organisms, these latter receive less and less encouragement. But their entry into rich wort in the fermenting back allows them a fuller play. As fermentation is carried on at present, many distinct fermentations proceed simultaneously, the high temperature favours them, and it is difficult to believe that the alcoholic yield is not sensibly diminished. Some experiments made on a large scale with fermenting wash at Bordeaux by Gayon and Dupetit, and described in the Society's Journal in 1886, confirm my contention, whilst some smaller ones made by Lindet on the effects of high fermentation heats show corresponding increases in fusel oil. We often find that at the high temperatures attenuation of the wash is completed in 24 to 30 hours from an original gravity of 1,050 down to or below water, but, in consequence of this haste, a yeasty wash is produced, containing as much as 0.5 per cent. of acid and literally swarming with disease organisms. Their products are, of course, strongly in evidence, most of these being included in the comprehensive term "fusel oil," the effect of which in the acidifier will be referred to. The high fermentation heats entail a loss of alcohol and ethers through evaporation, and much is carried away by the large volumes of CO_2 that are eliminated. This is found to be so when attempts are made to purify the escaping gases in the manner carried out at Guinness's brewery.

It may be remarked here that if the collection and purification of the CO_2 from fermenting vats could be made remunerative anywhere, it could surely be so at a large vinegar brewery, where the fermentations are conducted quickly and exhaustively, and at temperatures which must drive off the greater portion of the gas. I calculate that from a vat holding 10,000 gallons of wash fermented from 1,050 down to water the maximum quantity of CO_2 evolved is approximately $2\frac{1}{2}$ tons. With a close-covered back and two or three outlets for the gas, the removal being facilitated by suction, a high percentage of the maximum production could be collected.

As to the yeast crop, it is high time that vinegar brewers should endeavour to secure all or much of their pitching yeast. The economy ought to be effected in the same way that it is done at many distilleries, not only with regard to the pitching yeast but also with the view of supplying pressed yeast for the baker's use. Even if the high temperatures are adhered to these economies can be effected. An occasional all-malt brew might sometimes be advisable, the wash being mixed eventually with the grain wash, but even without this and with nothing but grain worts it is possible to secure most of the pitching yeast and to supply a large quantity of pressed yeast.

Of late some attention has been given to the subject of fractional fermentation both for analytical purposes, and as applied to beer manufacture. The products from pure cultivated yeasts or from moulds in different fermenting media have also been studied. Amongst many others who have worked in these directions there is Borgmann, who has found that with wort from a lager brewery, if a selected type of Carlsberg yeast be used, the ordinary alcohol ratio to that of glycerin in the products is increased, whilst the flavour produced is distinctive for any one variety of yeast. Ordonneau has published similar results both as to the quality and quantity of the alcohols produced. Gayon and Dupetit, by the aid of a species of mould, have been able not only to saccharify dextrin and starch but to cause the sugar so formed to ferment, whilst they have shown that the same organism in the presence of all the ordinary

products of alcoholic fermentation and of the residues which accompany them is still able to complete the main fermentation by saccharifying and fermenting the residual carbohydrates. Now these bodies are always present in the wash, and it is a matter worthy the attention both of distillers and vinegar brewers whether the sowing of appropriate quantities of these yeasts or of these moulds would in the time at their disposal be able to produce sufficient yield in alcohol to repay the trouble.

I have made a calculation with a view of showing the amount of vinegar at 6 per cent. acid that can be expected from the mashing materials usually employed, but as the loss of acid during acidification varies so considerably I will first state the results in wort which possesses an alcoholic strength of 5.75 per cent.

Taking malt 3 cwt. the quarter, and the wort produced at 1,050 original gravity (18 lb. per barrel), with good work 5 barrels, or 180 gallons, should be collected. Allowing 5 per cent. for waste during fermentation and removal to the acidifier, 171 gallons remain as the net estimated wort yield at 5.75 per cent. alcohol, it being assumed that attenuation is carried down to water.

In the same way, with malt and grain mixed (one-third malt and two-thirds barley, oats, and wheat) there would be a wort production of 200 gallons, which, less 5 per cent., leaves 190 gallons for acidification. With sugar of good quality, yielding per 1 cwt. a barrel at 42 lb., a net yield of 81 gallons of wort for acidification would result, or 243 gallons for 3 cwt.

With rice or maize in the raw state, and separately gelatinised, 1 cwt. would yield about 68 net gallons, or 204 gallons per 3 cwt. The gelatinised grists of rice and maize would yield still more.

Summarised, the estimated yields in wort of 1,050 original gravity would permit of the acidification of the following quantities of wash, viz.:—

Malt.....	3 cwt. 171 gallons,
Malt and grain	" 190 "
Rice and maize	" 204 "
Sugar (raw, good quality) ..	" 243 "

From the above figures some 5 to 20 per cent. must be deducted before ascertaining the final vinegar yield, the deduction varying according to mode of acidification. The cost per gallon of vinegar is found by dividing the actual yield in gallons into the cost per 3 cwt. of materials.

The distinctive operation at a vinegar brewery is the acidification. It aims at a rapid and complete oxidation of the alcohol to acetic acid, with the retention in the wash of any volatile products formed during the alcoholic or the acetic fermentation. An additional object is to form a vinegar which will keep bright under the ordinary conditions of exposure. It is therefore necessary by allowing time for settling, and by effective filtration, to introduce as bright a wort as is possible into the acidifier. This precaution delays the periodical sliming of the filling material, and accelerates the acidification. During the whole process the heat should be steadily regulated by means of the tin coil in the charging or in the receiving vessel. As the acidification slackens towards the end of the process in consequence of the smaller amount of available alcohol and the diminution in the amount of nitrogenous, carbohydrate and mineral food, means should be taken to supply these deficiencies and of maintaining the optimum temperature and increasing the air supply. A constant flow of warm air through the draught hole should be admitted, and means should be taken for condensing the large quantities of escaping fumes which are so rich in acid, alcohols, ethers, and aldehyde. The fumes should, when condensed, be made to trickle back again or be otherwise collected and returned.

The loss of acid usually taking place where no precautions of this nature are adopted, ranges from 6 to 20 per cent., the average is at least 12 per cent. estimating it upon the alcoholic percentage of the raw wash as compared with the acid percentage of the raw vinegar. The loss is generally attributed to evaporation, and it is increased if the up-draught is too powerful, for this carries away the nascent aldehyde. To further promote the acidification it is very

essential that the ferment and the fermentable liquid should be brought closely and constantly together—not merely intermittently. In the majority of cases this detail is imperfectly carried out, though of late, by the introduction of new filling materials and new methods of arranging them, the delay and loss have been minimised. Delay is sometimes due to the flooding of the acidifier with a cold, thick wort, or one rich in alcohol but very poor in nutriment for the acetic ferment; at other times an excessive and cold air-supply is admitted. The former case prevails when worts derived mainly from sugar are used and to which only just sufficient nitrogenous food has been added in the form of malt-extract to permit of alcoholic fermentation. So again, when worts derived largely from maize and rice grists are utilised. It has been recognised in alcoholic fermentation that with these descriptions of wort the nitrogenous food may be so diminished as to need the addition of yeast foods to complete the fermentation, but the idea has scarcely extended itself to the acetic fermentation. The addition of nitrogenous and mineral food for stimulating either the alcoholic or the acetic fermentation requires, however, the most careful management. Adrian Brown, in his paper on the "Numerical Increase of Yeast Cells," read before the Institute of Brewing in January 1890, showed that although a moderate quantity of nitrogenous food stimulated the fermentation, an excessive quantity interfered with it. Previously to this, viz., in June 1885, Salamon, in a paper read before this Society, had shown that in malt worts at any rate after the main alcoholic fermentation was complete, there always remained a large proportion of the nitrogenous matter which had existed in the original wort. He showed that similar results occurred with the salts of phosphorus. Notwithstanding these facts it is evident that in the fermentation, either alcoholic or acetic, of strong sugar worts, nitrogenous food certainly, and mineral food probably would be necessary to finish the processes.

There are other causes for loss and delay. The filling material may be too tightly packed, or may become so gradually, so that air cannot rise through it. The wash in such a case selects a natural course for itself in a series of channels, in which the slime accumulates. A thick, yeasty wash accelerates the sliming. Through the absence of an attenuator, the wash may undergo extreme variations in temperature, so that fermentative action is alternately weakened and strengthened. The exposure of a part of the acidifier to cold draughts chills the action. The filling material is but a poor medium for encouraging the continuous contact of wort, ferment and air. What is required is not merely the largest surface of exposure to aeration or to liquid, but a surface, which, like flannel, is absorptive or retentive of a large portion of liquid. The constant, rapid flow over materials such as smooth round twigs affords little time for the desired contact.

There are more intricate causes of dissatisfaction than any of these. The quantity and quality of the constituents of the wash exercise a powerful effect upon the fermentative action. Not only does the wash contain, according to its origin, more or less of the more prominent constituents such as the nitrogenous, mineral, and carbohydrate residue, but it contains, besides the main fermentation products, all the minor fermentation products, as well as the numerous species of ferments which originally created them. The alcohols higher than propyl in the ethyl series are not oxidised to their corresponding acids by the action of the ferment; not only is this the case, but there is reason to believe—guided by the researches of Adrian Brown—that the growth of the acetic ferment is directly retarded by these bodies. I believe I am well under the mark in stating that the higher alcohols in a vinegar wash at the close of the vinous fermentation, and when the wash is admitted to the acidifier, amount to $\frac{1}{2}$ per cent. of such wash, or range from 2 to 5 per cent. of the total alcoholic produce. Such a quantity must appreciably affect the action of the ferment. Then again there is the presence of many other ferments or micro-organisms to consider, and their continued action during the acidification period not only upon the alcohol present, but upon the other organic matter in solution. Take, for instance, the effect of some

varieties of the acetic ferment itself upon the large quantities of yeast in the wash and, in a minor degree, upon any dextrose or levulose residue. The slimy cellulosic matter formed by the continuous contact of these impedes the main process. So, too, with other specific ferments which abound in the wash, and which, for a time at least, must continue their work commenced in the fermenting vat, and so deprive the wash of appreciable quantities of acetic acid. Thus the lactic fermentation which sets in so powerfully at the high fermentation temperatures, not only tends to retard the attenuation, but competes with the acetic ferment for the appropriation of the nitrogenous and carbohydrate supplies.

An obvious remedy for many of the inconveniences occurring during acidification would be found in a method of sterilising the fermented wash in a close vessel, followed by filtering over materials steeped in vinegar or clear vinegar wash.

Perhaps a short explanation as to the general construction of acidifiers will make my previous remarks more clear. The usual acidifier resembles a large wooden vat some 15 to 20 ft. high, slightly tapering towards the top, the lower diameter being, say, 11 ft., and the upper 8 ft. The lower portion of the vessel, to the height of some 4 or 5 ft., is fitted with a block-tin coil, so that the wash that trickles into it from the higher portions may be kept at a uniform temperature of about 90° F. This part of the acidifier serves as a collecting tank, whence, by a pipe dipping almost to the bottom of it, the wash is pumped up to the top of the acidifier, where it is distributed over the top surface by means of a revolving sparger. The sparger, with the pump and pipe, are invariably made of ebouite or of wood. Immediately above the collecting tank is a stage which supports the filling material. This stage may be simply formed of crossed laths supported at the centre and side of the vessel, or the laths are themselves supported by stronger bars similarly held. In other cases the stage may be of strong wicker work, two or more pieces of it in one plane so as to form a complete stage or diaphragm. Upon the stage rests the filling material. Shavings of beech wood were formerly used, they required to be thoroughly steamed and then saturated with vinegar. The shavings were long and broad, and much trouble was taken in arranging them neatly to the height of some 4 or 5 ft. on one or more stages in the acidifier. Though shavings or even small chips are still employed in some places, they have been more frequently displaced by bundles of twigs. The tender twigs of birch or beech are tied up in small bundles, and, like the shavings, are thoroughly steamed and then saturated with vinegar and packed in layers on one or more stages, the total height being 4 to 6 ft. Resting upon the top surface of the filling material is a frame of wicker work, and just above this the sparger revolves. A clear space of two or more feet intervenes between this and the inside of the top cover, unless the sparger is fixed too high and revolves immediately below the cover. The cover fits close, but it is pierced with a few draught holes, which are usually kept plugged, or there may be a few such holes in the acidifier's circumference just below the cover. The escaping air, gases, and vapours have, as a rule, no other escape than through the small spaces between the planks of the cover, or through the interval between the cover and the circumference it rests upon. Just below the lowest stage of the acidifier are bored the draught holes, an inch or more in diameter and about 12 ins. apart round the whole circumference of the vessel. These are plugged when necessary so as to diminish the air supply. Air is also admitted in some vessels through the bottom of the vessel by a tube passing well up into the centre of the vat, and protected by a cowl.

Formerly there were some ingenious automatic arrangements for constantly feeding the vessel and dispersing the wash, but the pump and sparge arrangement has supplanted them. The air-supply is slightly warmed, for the acidifying chamber is kept warm by a stove or other heating arrangement, and the admission of cold air is regulated by a shutter.

A few years ago Shears and Manbré exhibited at the Brewers' Exhibition an acidifying tower consisting of a series of superimposed chambers. Each chamber consisted of a perforated floor supporting a portion of the filling material—shavings, I believe. Draught holes were pierced below each floor, so that aération was well provided for. The wash entered the top chamber and gradually trickled down through the whole series, meeting in its course fresh supplies of air. The bottom chamber was as usual fitted with a coil. The patentees claimed that the acidification was accelerated, the loss of acid vapours reduced, and the acidifying period was to be reduced from some eight or twelve days to at least half the time. I am not aware that any vinegar maker has adopted the invention, though it has been tried at one large brewery with the object of clarifying the condition of and increasing the acidity of soured beers so as to render them suitable for cutting isinglass.

I am inclined to believe that rapid acidification depends more upon the description of filling material than upon an increased air supply. A constant through draught of warm air and a constant shower of finely-divided wash are doubtless advantages, but a filling material of an absorptive or retentive character will facilitate acidification better than will one with a smooth, polished surface over which the wash easily glides. This idea evidently suggested itself some ten years ago to Edward Luck, and to some American inventors. They proposed, though in different ways, the substitution of the ordinary filling material by flannel or felt, or by other fabric. The Americans placed this material over a number of parallel hollow frames fixed in rows one above another. The air could surround the flannel on both sides, whilst the wash, after having traversed one frame, was guided on to the top of the one below it. The flannel when saturated with wash acted as a nucleus for the acetic ferment, and the wash slowly traversing it was in continual contact with the organism. Luck preferred strings, bands, or cords of the material. A large number of these were twisted tightly round wooden bars, and the wash was made to traverse these appendages by entering a groove or channel to which the strings were attached. I believe the new arrangement has proved most satisfactory. The same principle has subsequently been suggested by other persons though the internal arrangement of the acidifier was differently provided for.

Other recent improvements in acidifiers refer to means of creating a through draught by means of an exhaust fan, and to methods of condensing the escaping fumes and inducing a steady up-draught, but this is too large a field to be entered upon now.

Before closing this paper, I will venture a few remarks upon the discrimination of genuine from spurious vinegars, as the subject is one of some interest. For the manufacturer himself it is a comparatively easy matter to decide whether a given sample is his own or not. He has at his disposal all the ordinary analytical data with their limits of variation in his own particular produce to guide him. There is the final specific gravity, the percentage of fixed and volatile acid, the percentage of solid matter with its ratio of organic and mineral residue, and the amount of the different salts in the latter. Furnished with these and supported by the further observations which the outside analyst must rely upon, he cannot fail to recognise his own again. The analyst is often obliged to work without these data, and he has to distinguish between various kinds of vinegar. There is the genuine vinegar, but of all strengths; there are diluted vinegars which have been fortified with acetic acid and flavoured with acetic ether; there is distilled vinegar, a variety seldom met with; and there are the acetic acid preparations. Attempts have been made to decide upon adulteration by the ratio of two or more constituents or properties, such as specific gravity taken with the percentage of volatile and fixed acid, the various salts (especially the phosphates), and the nitrogenous matter. Now for all these determinations very wide limits must be allowed, for natural vinegars vary in strength from 6½ to 3½ per cent. of total acid. As to the nitrogenous matter, this also varies considerably, according to the materials used, a highly sugared wort or one largely derived from rice and maize being much poorer in this constituent than

a wort from malt and barley. Besides the nitrogenous matter is in many cases carried away to a great extent by the mineral findings in the final stages of clarification, whilst in other cases no fining operation is performed.

As to the varying proportions of phosphates and of nitrogenous matter in unfermented wort, and in the same wort when fermentation is complete, I may refer to a paper read before this Society in June 1885, by Salamon. Salamon found in worts produced from malt and sugar of varying qualities, that the amount of P_2O_5 ranged from a maximum of 0.197 grm. per 100 cc. of wort to a minimum of 0.086 grm., that is less than half the higher quantity. After the fermentation, with equal quantities of the same yeast, and without any disturbing influences, the residual phosphates ranged in amount per 100 cc. of the original volume from 0.153 grm. to 0.051, nor would any ratio between the original quantity and the residual quantity be established. As to the nitrogenous matter in the wort before and after fermentation, Salamon's experiments show that a mere comparison of the quantities originally and finally present would not help us here. In some cases the residual quantity was nine-tenths of the original in the wort, in others it was only four-tenths. The vinegar brewer's worts vary in strength from 1,030 to 1,060 gravity, and Salamon's experiments show that within these limits, with carefully regulated fermentations the residual nitrogenous matter yielded quantities of nitrogen per 100 cc. of original wort ranging from 0.03 grm. to 0.118 grm. These variations would probably be extended during the acetic fermentation, so that as quantitative tests, for the genuineness of vinegars the estimation of phosphates and nitrogen appears to me to be valueless. As qualitative tests the estimation is of some service, for phosphate and nitrogenous residues are always present in genuine vinegars however small those residues may be.

Variations from a given standard for vinegar residues are also due to the quality of the water employed in mashing, and to its treatment for brewing purposes, so that wide limits in the mineral residue must be made upon these accounts. The analyst must also allow for the use of preservatives and of colouring matter (both in moderate quantities) during the final stages of the vinegar process, nor should these substances be regarded as evidences of adulteration, but rather as legitimate and even necessary adjuncts.

Vinegar substitutes are frequently very cleverly prepared, and it is impossible in some cases to detect adulteration, unless the vinegar brewer will assist the analyst. Genuine vinegars will contain residues of carbohydrate, nitrogenous, and saline matter, and appreciable quantities of ethereal salts. Examined microscopically, they will be found to abound in the acetic ferment, though mostly the ferment is inactive; yeast cells too can nearly always be found. The acid substitutes will not contain these organisms, and usually they are stronger in acid percentage than a genuine vinegar. The coloured preparations will leave a caramel residue, but scarcely any nitrogenous residue.

DISCUSSION.

MR. A. GORDON SALAMON wished to ask Mr. Nettleton a question with reference to the "body" which vinegar-makers seemed desirous to obtain in their products. As far as the mashing temperatures were concerned, he would like to ask the author of the paper if he could give the approximate ratio between the maltose and the dextrine that should be formed, because that would influence very largely the flavour of the ultimate product, and also the attenuations which could be carried out. With reference to the preparation of his wort, Mr. Nettleton had dwelt upon the fact that it was not subjected to the hopping and boiling process obtaining in brewing; and yet at the same time he had emphasised the necessity of removing some of the nitrogenous matter. He would like to ask him, in that connexion, whether he had ever tried the use of gypsum in waters for the manufacture of vinegar. He had understood him to say that he had tried various salts. The consideration of the effect which would be produced by the action of gypsum on the water used for preparing

the worts was a matter of great interest, both from the theoretical and the practical point of view. He would also like to ask Mr. Nettleton what percentage of alcohol he would regard as the maximum one could venture upon in preparing the wort. If a malt vinegar were examined it would be found that there was a considerable residue left after the acid was removed, and his own experience led him to believe that there were limits in the preparation of the alcohol beyond which one must not go. He would like to hear Mr. Nettleton's views about those limits, and he thought it would be an advantage if he could define them. With regard to the question of analysis of malt vinegars, he would say that Mr. Helmer's method was an admirable one for estimating their purity; but he (Mr. Salamon) always took the phosphates in conjunction with the amount of acids, and he also took it with reference to the gravity; and he thought that if that were done a very accurate opinion could be formed as to whether the acetic acid was artificially added or naturally formed.

Mr. T. S. DAVIS would like to hear a little further discussion with reference to the question of fermentation. He understood Mr. Nettleton to say that in the alcohol fermentation for vinegar he considered it highly undesirable that air should be artificially introduced to a variable extent according to the rapidity of its progress. He (Mr. Davis) had had much experience in that direction, and had not found any benefit whatever from the artificial introduction of air through the body of the wort in the fermenting vessel. Mr. Nettleton had also referred to the fact that under certain circumstances he thought it desirable and economical to preserve the yeast obtained from one fermentation and add it to the next, just as a brewer would do. In his opinion, it was far better that the whole of the yeast should be allowed to deposit. He would also state, for the information of those not practically acquainted with the subject, that the cost of fresh yeast per 1,000 gallons of vinegar would be under 3s., and that as fresh yeast could always be obtained from a beer brewery, it was far more convenient to add such than to preserve that produced in a vinegar manufactory where brewings took place at irregular intervals, dependent on the rapidity of the subsequent acetifications. He advocated legislation as to the selling of vinegar below a certain standard. The strongest standard vinegars sold in London and the country usually contained about 6.3 per cent. of monohydrated acetic acid; but owing to competition the price had been much reduced, and in some instances cheap descriptions were sold containing as little as $2\frac{3}{4}$ per cent., and he did not consider that vinegar sold at that strength was worthy of the name. He would also like to be allowed to make an observation with regard to distilled vinegar, of which a large quantity was manufactured, and was principally consumed in the North of England. This was produced in two grades; one was a vinegar distilled from a pure malt vinegar, and another was diluted acetic acid distilled from sodium acetate. There was a certain amount of ether present in pure distilled malt-vinegar, which rendered it both different in flavour, in character, and in aroma from that which could be produced from any other source. A short time ago a case came before a court of law as to whether the distillate from a pure malt vinegar could be correctly described as "malt vinegar." A certain analyst announced in court that a sample had no right to be so called, inasmuch as the phosphates had been separated therefrom, thus making it simply pure acetic acid, and this assertion was supported by the judge. This view was erroneous, because the acetic acid was flavoured with an aroma which could not be separated therefrom by distillation, but to prevent any future erroneous nomination, the vinegar is now described as "white vinegar distilled from pure malt vinegar." This description is accepted as satisfactory, both on the part of the analysts and consumers.

Mr. NETTLETON, in reply, said that he entirely sympathised with the remarks made by Mr. Davis in reference to the fixing of a standard. He was of opinion that 2 per cent. was far too low a standard at which vinegar should be allowed to be sold. It was well known that at least 90 per cent. of "white vinegar" was the product of the distillation of acetate of soda. In reference to the question of yeast, he quite concurred

in the view that there might be practical reasons why vinegar brewers did not hold over yeast from one brewing to another; but he thought there might be other ways of disposing of it. In alcoholic fermentations there was a vast amount of yeast wasted, and it was only during recent years that distillers began what had now become an enormous trade in pressed yeast, and yet even they could also use some of their yeast after a time for their own fermentations. For his own part he could not see why vinegar makers should not do the same. He could see many points in favour of occasionally purchasing barrels of yeast from the beer brewer; and he also recognised that if brewings only took place periodically, or a long interval lapsed between two different brewings, this would have to be done. The only other course he could see was to have some system of washing and preserving the yeast. As to the question of air. Of course an acidifier would not always work well, but as a rule he thought acidifiers had quite a sufficient air supply; but it should be remembered that the air was sometimes supplied at a temperature of 60°, at other times at one of 70° or 80° F. He thought there were more improvements to be made in the direction of regulating and distributing the air at a suitable temperature, such as 80° or 85°, than by admitting a larger quantity. He presumed Mr. Salamon's question with reference to the standard of alcohol in wort was dictated by a wish to know what would be the most economical arrangement to carry out. Thus, assuming that worts could be obtained at a very high specific gravity, and that consequently a large yield of alcohol were obtained, and that such alcohol could be completely acidified, what would be the highest percentage of alcohol that should be found in the wort?

Mr. SALAMON explained that he meant the proportion of alcohol in the practical limits of work.

Mr. NETTLETON replied that in Brant's work on vinegar a certain limit was quoted, beyond which it would not pay to have the alcoholic strength in the wort; but whether that limit was 10 or 12 per cent. he could not remember. Such a high standard as that of 10 or 12 per cent. absolute alcohol was never reached in practical work.

Mr. SALAMON further explained that his object in asking the question was, that he understood Mr. Nettleton to say that the vinegar maker fermented his wort below 1,000, and therefore he was anxious to know the percentage of alcohol.

Mr. NETTLETON explained that supposing a wort of very high specific gravity, say 1,080, were taken, it would be quite possible to ferment below 1,000, but he questioned whether it would be wise to have such a very high alcohol percentage. He did not think that such strong wort would undergo acetic fermentation, because so much acid would be formed that he believed the acetic ferment would not be able to cope with the residual alcohol, and unconverted alcohol would remain. He was aware that there was a system of acidifying by which a very strong wort could be used, the wort being passed first through one vessel so constructed that it would induce acidification up to a certain point, and then through two others which finished off the acidifying. But this was a very complex process, and he did not think it was used in this country. He was of opinion that in ordinary worts it was desirable to ferment down as low as possible.

Mr. SALAMON asked whether he was right in understanding that any dextrin formed during the process of washing underwent fermentation.

Mr. NETTLETON admitted that there must be a residue of dextrin, but whether it was solely responsible for the "body" which existed in vinegar he doubted, for there was also a nitrogenous residue. He thought that the use of gypsum in moderate quantities was very desirable. Gypsum was supposed to exercise a clarifying influence upon the wort. In the case of vinegar brewing, such action in the mash-tun had alone to be relied on, for extra clarification could not be produced as there was no boiling operation. So far as its action in the mashing and fermenting processes were concerned he would say that gypsum in very moderate quantities was a most beneficial salt to use.

ON CERTAIN ALUMINIUM ALLOYS.

BY C. R. ALDER WRIGHT, D.S.C., F.R.S.

It is well known that whilst, as a general rule, molten metals are miscible with one another in all proportions, there are a small number of well-marked exceptional cases where the two metals behave to one another as ether and water when shaken together, *i.e.*, two such metals, A and B, when intermixed molten give a mixture of two alloys which separate from one another by gravitation on standing molten for a sufficient time; one, consisting chiefly of the heavier metal, A, and as much of the lighter one, B, as it can dissolve at the temperature prevailing, the solubility being greater the higher the temperature; the other mainly consisting of B, with as much of A as is permanently soluble therein at that temperature. For instance, when A is lead or bismuth, and B zinc, the immiscible binary alloys formed have the following compositions* deduced from the average of a large number of determinations:—

Temperature.	Heavier Alloy.		Lighter Alloy.	
	Lead.	Zinc.	Lead.	Zinc.
Near 650°	98.76	1.24	1.14	98.86
„ 800°	98.70	1.30	1.57	98.43
	Bismuth.	Zinc.	Bismuth.	Zinc.
Near 650°	85.72	14.28	2.32	97.68
„ 750°	84.82	15.18	2.47	97.53
„ 800°	84.17	15.83	2.52	97.48

On the other hand, when lead (or bismuth) is mixed with melted tin a homogeneous fluid results, exhibiting no tendency whatever to separate into two different alloys, no matter how long the mass is allowed to stand molten.

It does not, however, follow that because a mixture of two (or more) metals remains perfectly homogeneous whilst standing at rest molten at an equable temperature, therefore the mass will solidify as a uniform whole; or that if solidified, the ingot will not “liquefy” on heating again, a more fusible alloy running away from a less fusible one of different composition. In fact, the reverse is very frequently, if not almost invariably, the case, the forces coming into play when change of state occurs being wholly different from those at work when the whole mass is kept always liquid.

The author has recently made a number of observations on various aluminium alloys, some of the results of which are wholly at variance with the usually received notions on the subject, as described in the text-books. Thus he finds that from the point of view of complete or imperfect miscibility with other metals whilst molten, aluminium presents a close resemblance to zinc, in that it will not mix in all proportions with lead or bismuth, mixtures of this kind separating on standing molten into two alloys, one consisting of lead (or bismuth) with a minute quantity of aluminium dissolved therein; the other chiefly consisting of aluminium with a small quantity of the other metal. It differs, however, from zinc in not mixing in all proportions with cadmium. On the other hand, mixtures of aluminium with most other metals (notably tin, silver, zinc, antimony, &c.) give homogeneous fluids exhibiting no tendency to separate into different alloys whilst standing molten, provided the temperature is sufficiently high to keep the whole mass fluid; if, however, the temperature be low enough to permit of a solid less fusible alloy separating, this sometimes occurs, especially with antimony.

These results as regards bismuth, cadmium, and antimony are very far from being in accordance with the usual book

statements. As regards lead, it was originally observed by Deville, and subsequently by Tissier and others, that the two metals will not mix when melted and stirred together. Tissier found that antimony behaved in the same way, and the statement that the two metals are not perfectly miscible is accordingly copied into the text-books, although this is very far from being the case. On the other hand, Tissier found that bismuth and aluminium combine readily, forming fusible alloys which oxidise very rapidly when melted, and are also very alterable in the air at ordinary temperatures when the bismuth is in large proportion. This description applies accurately to certain of the antimony aluminium alloys (not to all, some being comparatively infusible); but is quite incorrect as regards bismuth and aluminium, inasmuch as these two metals are as immiscible as are zinc and lead. The alloy containing 10 per cent. of bismuth described by Tissier as hard and malleable does not exist.

According to Deville, cadmium unites easily with aluminium forming malleable and fusible alloys capable of being used to solder aluminium, but only imperfectly. The author, on the other hand, finds that cadmium and aluminium are as immiscible as bismuth and aluminium, or lead and aluminium.

The source of these inaccuracies, in all probability, lies in the circumstance that when mixtures of metals not completely miscible together are well incorporated by agitation, what is formed is a sort of metallic froth or emulsion, which in many cases requires a very considerable time before it completely separates into two different fluids; so that if the fused mass is solidified before this separation has taken place, a product is obtained consisting of a more or less intimate mechanical intermixture of two entirely different substances. If, on the other hand, the fused mass be poured into a hot long narrow crucible (like a long clay test tube), and maintained molten at an equable temperature for eight hours and upwards (preferably by immersion in a bath of melted lead), the two constituent binary alloys gradually separate from one another, in some cases completely, so as to give a well-marked line of demarcation between the two, as with a froth of ether and water, or water and chloroform, allowed to stand until complete separation takes place; in other cases less thoroughly, but in such fashion that the lowest portion of the fluid mass consists of the heavier alloy with little or no admixture of suspended particles of the other, and *vice versa*, with the uppermost portion: the middle part consisting of the two still mechanically intermixed, much as a frothy mixture of ether and water containing soapy or mucilaginous matters often behaves under similar conditions. In all such cases when the clay test tube is removed from the lead bath and quickly cooled down, the contents solidify to a thin compound bar, easily obtained by breaking away the clay; with a tube of $\frac{1}{2}$ to $\frac{3}{4}$ -inch internal diameter and 5 to 7 inches long, filled half or two-thirds full of metal, the bar is generally solidified sufficiently rapidly to prevent any material alteration in the normal composition of the two alloys constituting its ends, through liquation or segregation during solidification, although such an action is obviously not impossible, and indeed with very slow cooling is sometimes noticeable.

When aluminium and tin (or silver) are fused together, well stirred, and maintained molten for eight hours in a lead bath, the bar finally obtained gives on analysis sensibly the same results, whether the portion employed be cut from the extreme bottom, the middle, or the uppermost part of the bar, indicating perfect miscibility of the two metals whilst fluid. If, however, lead or bismuth be used as the second metal very different results are obtained; provided that the molten mass has stood long enough to bring about proper separation, the heavier end of the bar consists almost entirely of lead (or bismuth) with only a minute quantity of aluminium; whilst the lighter end consists of aluminium with 1 to 2 per cent. of the heavier metal. If, however, the separation has been less complete, more or less considerable increment is observed in the aluminium found by analysis of the heavier end and of the lead (or bismuth) found at the heavier end. The following figures were obtained on analysis of a number of such binary alloys, the aluminium only being determined at the heavier

* Alder Wright and Thompson, Roy. Soc. Proc. 45, 461; 48, 25; and 49, 156.

end, and the lead (or bismuth) at the other end; the temperature of the lead bath throughout was between 750° to 850°, averaging near 800°, as determined by the platinum specific heat pyrometer. The period during which the mass stood at rest molten was usually eight hours.

On comparing these results with those above quoted obtained with zinc instead of aluminium, it is obvious that notwithstanding the slightly higher temperature, the solubility of aluminium in lead or bismuth is markedly less than that of zinc in these metals respectively, especially in bismuth. The solubility of lead in aluminium, on the other hand, is slightly greater than that of lead in zinc; whilst the solubility of bismuth in aluminium is slightly less than that of bismuth in zinc, the difference not being very great in either case.

It results from the incomplete miscibility of molten aluminium with fluid lead or bismuth, that when a third metal is added to a mixture of aluminium and either of these metals, such that this third metal is miscible in all proportions with either aluminium or lead (or bismuth), the ternary alloy formed will either be "real,"* exhibiting no tendency to separate into two different ternary alloys, or "ideal," i.e. incapable of permanent existence, separating on standing into two different ternary alloys, according as the mixture represents a point lying outside or inside the "critical curve" for the three metals employed at the temperature of the experiment. The data for the delineation of the critical curves for various mixtures of aluminium and lead (or bismuth) with appropriate third ("solvent") metals are being accumulated.

When aluminium and cadmium are melted together and well stirred, they behave in a fashion much resembling that observed with lead (or bismuth) and aluminium, on standing at rest molten for some hours, cadmium containing only a few tenths per cent. of aluminium, sinks to the bottom, whilst aluminium containing between 2 and 3 per cent. of cadmium floats up to the top.

On examining the behaviour of aluminium when melted along with antimony some remarkable results were obtained, leading to the conclusion that with certain proportions alloys are formed exhibiting melting points much above those of either antimony or aluminium; so that unless the temperature of the mixed metals is considerably elevated, the whole mass sets solid, or at any rate so pasty as to be incapable of being poured out from the crucible. With mixtures containing from 15 to 25 per cent. of aluminium and 75 to 85 of antimony, the temperature of complete fusion of the mixture appears to be quite as high as that of silver. Thus, on melting aluminium in a small Fletcher's blast gas furnace, and then adding the antimony in lumps, the latter rapidly melted down and sank to the bottom of the crucible, the fused aluminium floating on the top; on continuing the heat for a few minutes so that the whole mass was well above the melting point of silver, and stirring up with a clay rod previously heated nearly white hot, the two metals quickly intermixed, and then set to a nearly solid mass. When the proportion lay between 10 and 15 of aluminium to 85 and 90 of antimony, or between 25 and 35 of the former to 65 and 75 of the latter, the mixtures remained fluid at temperatures above the melting point of silver; but on continuing the stirring at a slightly lower temperature they became pasty, a precipitation of a solid alloy obviously occurring. By carefully pouring off the yet fluid portion when this occurred, putting down the solidified or pasty mass in the crucible with a red hot clay pestle, so as to squeeze out as much fluid metal as possible, the contents of the crucible could be divided into two portions, viz., the more fusible alloy poured off, and the almost solid residue. This latter, on cooling, formed a brittle, highly crystalline mass; when the mixed metals were in the proportions of 18—19 aluminium to 81—82 antimony, very little fluid alloy could be thus expressed, and this differed but little from the unfused portion in composition; with mixtures richer in aluminium the more fusible alloy always contained considerably more aluminium than the less fusible residue; whilst with mixtures poorer in aluminium the reverse was the case; strongly suggesting that the precipitated solid alloy essentially consisted of a definite compound indicated by the formula $AlSb_3$, which requires—

	Per Cent.
Al.....	18·4
Sb.....	81·6
	100·0

together with more or less considerable intermixture of mechanically adherent more fusible alloy containing excess of aluminium or of antimony, as the case might be.

When the proportion of aluminium present in the mixture was less than about 10 per cent., it was found difficult to regulate the temperature so nicely as to bring about the precipitation of this comparatively infusible alloy; but on allowing the mass to cool and solidify, and then raising the temperature again, so as to cause a portion to melt and liquefy away from the rest, it was found that the portion thus melted contained more antimony relatively to the aluminium than the unmelted portion; indicating as before that the latter was $AlSb_3$ together with an admixture of more fusible alloy, containing in this case excess of antimony.

Precisely similar results were obtained when the proportion of aluminium present exceeded about 35 per cent., excepting that in this case the portion liquating away from the rest contained more aluminium relatively to the antimony than the less fusible portion.

Whether the proportions of aluminium present were below or above 18·4 per cent., in all cases if the temperature were high enough the whole mass melted to a uniform fluid easily poured off from the scorifier which formed somewhat rapidly on stirring; to diminish this tendency the air-blast was so regulated as to keep the flame reducing rather than oxidising. When the melted metal was poured off into a brightly red-hot clay test tube and kept fused for several hours at a temperature of 900° C. and upwards, no marked difference in composition between the top and bottom ends of the resulting ingot was noticeable,

* Vide this Journal, 1892, p. 245. Abstracts of papers by the authors and collaborateurs read before the Royal Society.

showing complete miscibility of the metals when thoroughly melted. With the smaller percentages of aluminium the resulting alloys were brittle and crystalline, and differed little from antimony in appearance; on keeping in the air, especially when coarsely powdered, they absorbed oxygen and slowly disintegrated to a black powder, not unlike manganese dioxide. The alloys richest in aluminium were generally somewhat spongy; they also absorbed oxygen from the air slowly, the ingots swelling up and falling to powder on keeping.

The difficultly fusible substances that precipitated solid from the molten mixtures containing intermediate proportions of antimony (more or less impure AlSb) showed the greatest tendency of all to absorb oxygen and disintegrate to black powder, a considerable gain in weight being usually noticed if fragments were weighed and left on the pan of the balance for some hours. When placed in water a slow evolution of hydrogen was generally noticeable, becoming strongly marked on heating the water to near its boiling point. The gas thus evolved appeared to contain small quantities of silicuretted hydrogen (derived from traces of silicon contained in the aluminium used) as it slowly browned white paper moistened with silver nitrate; but on burning, no antimonial spots were produced on cold porcelain, and only very faint indications of antimonial mirrors were formed on passing through a red-hot narrow combustion tube for half an hour at a time; so that antimonuretted hydrogen was practically not evolved at all.

The following numbers were obtained on analysis of a series of products formed with mixtures of aluminium and antimony where the former varied between 8 and 36 per cent. of the whole mass. The aluminium used was commercially pure metal (so-called 99 per cent., containing small quantities of silicon and iron, but otherwise pure); the antimony was pure metal prepared from tartar emetic. The analysis was made by dissolving in dilute hydrochloric acid containing a little nitric acid, precipitating the antimony by means of sulphuretted hydrogen, collecting on a weighed filter, and finally heating a portion of the mixed precipitate of sulphur and antimony sulphide in an atmosphere of carbon dioxide. The aluminium was precipitated from the filtrate by ammonia, and the weighed alumina corrected for traces of silica and ferric oxide. In each case the figures are calculated on the sum of the aluminium and antimony found as 100:—

	Percentage of Al originally employed for Fusion.	Comparatively Infusible Residue.		More fusible Alloy poured off.	
		Aluminium.	Antimony.	Aluminium.	Antimony.
1.	36	27.25	72.75	55.00	45.00
2.	32	26.75	73.25	38.55	61.45
3.	29	24.50	75.50	31.75	68.25
4.	23.5	21.00	79.00	27.75	72.25
5.	21	18.78	81.22	21.28	78.72
6.	20	19.42	80.58	18.35	81.65
7.	15	15.23	84.77	12.98	87.02
8.	8	7.55	92.45	5.60	94.40

The mixtures marked 1 and 8 were *liquated*, i.e., after fusion the mass was allowed to solidify, and then by raising the temperature a portion was melted which was poured off, leaving the unmelted part behind. The other mixtures, Nos. 2 to 7, were prepared by melting the aluminium, adding the antimony which melted and sank to the bottom, and then stirring well together with a red-hot clay rod, the temperature being so regulated that during the stirring a portion of the alloy precipitated in the solid form. With Nos. 5 and 6 the temperature was judged to be above the melting point of silver, and very little fluid alloy could be poured off; with the other mixtures the temperatures were somewhat lower, but not much.

With the mixtures numbered 1 to 4, the proportion of aluminium originally used was above that corresponding

with the formula AlSb; and in these cases the more fusible alloys contained much larger proportions of aluminium than the comparatively infusible residues. With Nos. 5 and 6, the original compositions differed little from AlSb; in these cases the more fusible alloy obtained was very small in quantity, and differed comparatively little from the less fusible portions. With Nos. 7 and 8 the proportions of aluminium originally employed were below that corresponding with AlSb; and in these cases the more fusible portions contained excess of antimony as compared with the others. In all cases, therefore, the relative values are just such as would be obtained by the separation out from the molten mass of a solid compound AlSb, this compound necessarily remaining wetted, as it were, by the more fusible alloy when this latter is poured off as far as possible.

On contrasting the temperatures of complete fusion of a series of alloys starting with pure antimony and going up to AlSb, it is evident that the melting point continuously rises up to a value considerably above the melting point of pure aluminium; when the aluminium present exceeds that contained in AlSb the melting point falls again, the maximum being with the composition AlSb. A precisely similar state of things has been recently shown by Professor Roberts Austen to occur with aluminium-gold alloys,* excepting that the maximum is found for the definite purple-coloured compound Al_2Au , and not for a compound containing only one atom of each metal.

DISCUSSION.

The CHAIRMAN said that he was going to ask Dr. Wright what was the practical application of the alloy, but when the samples were seen the hopes of practical application were at an end. The question of oxidation was exceedingly interesting, and the absence of antimonuretted hydrogen was a very singular fact. With regard to the compounds from which the samples were reduced, he had had a good deal of experience in purifying commercial bismuth, and he had found that in ordinary methods of fusion the bismuth adhered to, or, in the author's words, dissolved considerable fractions of impurities, so as to render the production of pure bismuth, as distinguished from ordinary commercial bismuth, a matter of considerable difficulty. But it had been done. Although the immediate practical results of Dr. Wright's investigations in this connexion were not apparent, yet the value of such researches would be seen when they appeared in the Journal.

ON OIL AND IRON STAINS IN COTTON CLOTH.

BY CARL OTTO WEBER, PH.D., F.R.S.

OIL stains in cotton cloths are an occurrence well known to every bleacher and dyer, and it is the general experience that their complete removal is effected in the kiering process. This is absolutely certain where the oil stains have been caused by animal or vegetable oils and greases, as in this case under the circumstances obtaining in kiers, the saponification of these oils completely removes the stains. Not quite so simple is the case if the stains are caused by mineral oils. These are incapable of saponification, but as soap solutions (especially alkaline ones) dissolve considerable quantities of mineral oils, it is generally assumed that the rosin soap employed in the process of kiering emulsifies, and eventually dissolves also these stains. This may be true as long as the stains are fresh, but it applies not to old stains, which through long exposure to the air have undergone oxidation. Cloth containing such mineral oil stains cannot be effectively dealt with in an open kier, although in a pressure kier and conditional to a liberal supply of rosin soap, the stains practically disappear, *i.e.*, they can no longer be seen, and in the process of printing or dyeing such cloth, nothing occurs that would indicate that these oil stains are still in existence. Iron stains perhaps occur not so often in cloth as oil stains and may prove a great nuisance occasionally, but under ordinary circumstances their removal is easy enough. If the stains are few and far between, they are treated one by one with a moderately strong solution of oxalic acid, the piece being subsequently washed. If there are too many of these stains in a piece to apply this treatment, padding in a bath of oxalic acid at 5° Tw. or in bisulphite of soda at 7° Tw. will answer. If, however, oil and iron stains appear in the same piece, forming as it were one single stain, the question of getting rid of these combined stains is in most cases a matter of very considerable difficulty, the oxidised oil retaining the iron stain even against concentrated solutions of oxalic acid or strong sulphurous acid; even the most powerful agent for removing iron stains, a solution of tin oxalates in hydrochloric acid has not the slightest effect on these compound stains. I may at once say that I do not know of a case of these stains ever being found in grey cloth, or being produced in the course of the bleaching process, although the single oil or iron stains are common enough at this stage. But the compound stain inevitably forms when oil-stained cloth is dyed with an iron mordant. The faintest trace of an oil stain left in the cloth can be found out by treating a suspected sample in a bath of ferrous or ferric sulphate, and producing the well-known iron buff by afterwards passing through weak soda carbonate. As a rule the stain does not show in the buff, but after stripping the colour in any suitable acid bath, a bright iron stain remains wherever the cloth retained the least trace of an oil stain. From this it is clear that in the majority of cases these compound stains will never be noticed, unless the cloth is stripped of its dye. Unfortunately the latter process is frequently necessary in the case of drab twills, which have at times from some unaccountable reason an awkward tendency to bleach in the folds, or to come up a wrong shade in dyeing. For the purpose of re-dyeing such pieces the colour is stripped and then the oil stains become visible as bright iron stains. On re-dyeing these pieces in the manner generally used for this class of goods, by first giving two ends in a mixed bath of fustic, sumac, and annatto, and afterwards fixing in a bath of ferrous sulphate, these iron stains do not disappear but show as ugly olive patches. That these stains show only in the second dyeing is easily accounted for, as they now contain twice as much iron as the rest of the piece. It is therefore evident that, before re-dyeing pieces stained in this manner, it is absolutely necessary to first remove these stains. I have already mentioned the obstinacy with which these stains resist all ordinary agents, and the cause of this, no doubt, is that we have the iron here in the form of an iron soap. Taking

this into consideration, there is no doubt that the iron stain will only yield if treated with an agent, which at the same time loosens the oil stain. After a great many experiments, I found that by padding such pieces in a hot solution of one part of soft soap, one part of glycerin, and three parts of water, taking through squeezing rollers, letting lie for 24 hours, then washing, the iron stains, together with the oil stains, are completely removed. The rationale of the process will be readily understood if we remember the great ease with which oils of every description dissolve in solutions of glycerin and soap, and also the capability of alkaline glycerin solutions to dissolve ferric oxide in large quantities. The price of the process amounts to about 3s. per 100 lbs. of the cloth, and from this the price per piece may easily be calculated, the weight of a piece varying from 26 to about 80 lb.

The whole difficulty about these compound stains would of course best be dealt with by taking care to remove every trace of oil in the cloth in the kiering process, but as I have already remarked, this is a matter of considerable difficulty in the case of mineral oil stains, although pressure kiers are as a rule fairly efficient in this respect. From experiments carried out on a large scale, it appears, however, that this difficulty can be overcome by deliberately increasing the mineral oil stain in the grey cloth, by adding a vegetable oil to it. Treatment even in an open kier is then quite sufficient to remove every trace of an oil stain.

TURKEY-RED OIL.—PART II.

BY J. ARTHUR WILSON.

THE results contained in this paper are a brief *résumé* of an extended investigation into the best method of detecting and approximately determining the adulterants of Turkey-red oil. The most common, and at the same time the cheapest adulterant is, of course, water, but as most buyers and users of this material stipulate for a certain percentage of fatty matter, it is necessary to use some cheap oil in place of water. Cotton-seed oil is possibly the most used, and I may say that I have reason for believing that a large amount of adulterated Turkey-red oil is made and used. It is as well to remember that a manufacturer of oil may unwittingly prepare an adulterated article. I mean, of course, by the use of adulterated castor oil. The writer has submitted the fatty matter prepared in a definite manner from Turkey-red oils made from genuine castor oil, also from castor oil containing other oils, to the usual methods of analysis of oils and fats, and more especially to Benedikt's acetyl process, but it is to be regretted that none of these methods alone give evidence sufficient to condemn or pass a sample. It is the careful consideration of the results of the *whole* of the tests on which one must rely. These tests are, 1st. Specific gravity, combining weight, point of congelation of fatty acids, iodine value, and acetyl value.

Before describing the results of my investigations, it is necessary to mention the method of preparation of the fatty matter for analysis. 100 grms. of the sample are taken in a 24 oz. flask, to which is added 250 cc. of methylated spirit and 20 grms. pure caustic potash. A long tube is attached and the flask and its contents kept for one hour on the water-bath with frequent agitation. The alcohol is then evaporated and about half a litre of water added, containing sufficient pure hydrogen sulphate to decompose the soap and leave a moderate excess. A piece of pumice coiled with platinum wire is added and the contents of the flask kept in gentle ebullition for one hour. The flask is allowed to stand and the aqueous layer syphoned off, and the fatty acids washed three times with hot water, dried on the hot filter, and then by heating in a porcelain dish for a short time. The fatty matter thus prepared is used for the above determinations.

The results of my investigation are as follows: The specific gravity of the fatty matter prepared as above from genuine castor oil varies with the proportion of vitriol used

in the manufacture of the Turkey-red oil, but only to a small extent, whilst on the other hand, olive and cotton-seed oil are much more affected. The average density of the various acids taken by the Westphal balance at 98° C. are:—

Nature of Oil.	Specific Gravity at 98° C.
Castor oil acids	892.0
Olive oil acids	851.0
Cotton oil acids	872.0

The point of congelation of the fatty acids is often very useful. The fatty acids of Turkey-red oil from castor oil do not deposit any, or the merest traces, of solids at 15.5° C. Olive oil and, still more, cotton-seed oil acids deposit much solid matter at the above temperature. The melting point of the acids from olive oil and cotton-seed oil as determined by the capillary tube pressure method are:—

Melting point of cotton-seed oil acids	41° C.
Melting point of olive oil acids	40°

The combining weights of the fatty acids are too near one another to be of any service whatever. Thus we have:—

Nature of Oil.	Mgms. of KHO per 1 grm. of Fatty Acid.
Castor oil	180—184
Olive oil	173—176
Cotton oil	171—175

The iodine value is also very variable, and besides being dependent on the age, &c. of the oil used, is liable to considerable fluctuations, by the method of preparing the Turkey-red oil, especially on the amount of vitriol used. On this account it is not to be strongly recommended.

The method on which the most reliance is to be placed is undoubtedly the acetyl value. I may remind members who may not be acquainted with this process that it consists of the introduction of acetyl groups into the substance and subsequent elimination by saponification, and estimation of the alkali required for this removal. It is, notwithstanding the remarks of Lewkowitsch, a most valuable process, and is certainly a very valuable addition to our methods of examining oils and fats. The process is worked as follows: The dry fatty matter is heated to boiling for one and a half hours under a reflux (dry) condenser with four-fifths of its weight of dry acetic anhydride, and the acetylised acid washed with hot water till the wash-water is neutral to delicate litmus paper, when the fatty matter can be dried as quickly as possible. A weighed quantity of about 2.5 grms. is then titrated in alcoholic solution quite cold with semi-normal alcoholic potash, and the amount noted. A further quantity of alcoholic potash about 1½ times more than the first quantity is added, and the flask kept 30 minutes on the water-bath with a long tube attached. After this time the residual alkali is estimated by semi-normal hydric chloride. Phenolphthalein is used as indicator in both cases. The alkali used in the first instance is calculated to milligrammes per 1 grm. of fat, and is termed the acid value. The total alkali is calculated in the same way and is termed the saponification value, the difference between the two is the acetyl value.

The three chief oils for Turkey-red oil manufacture show when thus tested:—

Nature of Oil.	Acid Value.	Saponification Value.	Acetyl Value.
Castor oil	136.7	291.7	155
Olive oil	170.0	206.0	36
Cotton-seed oil	189.5	210.5	21

Owing to the interactions between the glycerides and the vitriol in the manufacture of the Turkey-red oils the differences are not so apparent. The following table shows the results to be expected:—

Nature of Turkey-red Oil.	Acid Value.	Saponification Value.	Acetyl Value.
Castor oil, maximum	141.0	287.4	146.4
Castor oil, minimum	140.2	287.9	138.7
Olive oil	158.7	205.0	106.3
Cotton-seed oil	179.0	232.0	53.0

The determination of the iodine value before and after acetylisation, affords a check on the latter determination. Useful information is also afforded by a determination of the solidifying and melting point before and after acetylisation. If mineral or rosin oil were present they would of course be separated and estimated in the usual manner.

SOME FURTHER NOTES ON NITROGEN IN COAL-GAS.

BY GEORGE E. DAVIS.

FOLLOWING the reading of a paper at the last meeting of this Section, by Mr. C. H. New, on the determination of nitrogen in coal-gas, a discussion occurred in which some doubts were expressed as to whether such a large amount of nitrogen as 14 per cent. could possibly exist in a gas supply, seeing that Professor Vivian Lewes had examined a sample of London coal-gas which contained less than 1 per cent. of nitrogen. It was also pointed out by Mr. Stenhouse that if 15 per cent. of nitrogen were present due to the pumping in of air, there should be at least 2 per cent. of free oxygen, the presence of which the reader of the paper had not recorded. I saw that the argument used by Mr. Stenhouse would at once prove the accuracy or otherwise of Mr. New's results, and on Saturday, May 7th, the day after the reading of the paper, I decided to make an examination of the gas for oxygen, nitrogen, and illuminating power, concurrently. At 10 a.m., and when it might be supposed that the night gas lay dormant in the pipes, I found the gas contained 1.1 per cent. of oxygen, and its illuminating power 15.6 candles. At 12.30, after the gas had been burning the whole interval in the laboratory, tests were again made, with the following results:—

	Per Cent.
Oxygen	2.1
Nitrogen	13.9
Illuminating power	13.6 candles.

I think this shows clearly enough that there is a difference between the night gas and the day gas, and that the difference in illuminating power is chiefly due to oxygen and nitrogen. Why this is so I do not pretend to explain. I have made some further tests with reference to the percentage of nitrogen. The day tests on the 18th instant were 8.28 per cent. of nitrogen with 1.08 per cent. of oxygen. On the 23rd the day gas contained 8.67 per cent. of nitrogen. The night tests contained less nitrogen. On the 16th, taken at 8 p.m., the percentage of nitrogen was 7.3; on the 17th it was 7.4, with 1.5 per cent. of oxygen; on the 19th, at 7.30 p.m., it contained 5.6 per cent. of nitrogen; on the 20th, at 10.30 p.m., it contained 7.4 per cent. of nitrogen; and on the 22nd, at 8 p.m., it contained 7.75 per cent. Between the 16th and 23rd the illuminating power varied from 13.2 candles in the daytime to 15.6 candles at night.

Compared with Professor Vivian Lewes' figures of the London gas, we appear to have a very different mixture in Salford, and the low illuminating power as recorded upon our photometer is clearly explained. How this nitrogen and oxygen gets into the gas is a matter I

have not considered, and these facts seems to be borne out by some further figures from Professor Lewes. He finds that 100 volumes of gas require about 230 volumes of either air or nitrogen to reduce its luminosity to nil, a quantity which certainly does not agree with the earlier notions of gas engineers. In the Salford gas there exists at the utmost 14 volumes, and, as a general thing, 7 to 8 volumes, which is about the proportion necessary to reduce the illuminating power from 18 to 14 candles, if reckoned as a diluent, combined with a certain amount of light-destroying power. Hunter, in his lecture at Salford (published by J. and E. Cornish, Manchester) in 1878 states (p. 32) that 10 per cent. of air added to 25-candle gas reduced its illuminating power to 8·25 candles. Under extraordinary conditions this might be so, but I think I have shown that it is possible to have 11 per cent. of nitrogen and 2 per cent. of oxygen in 14-candle gas.

DISCUSSION.

MR. STENHOUSE (Rochdale) said that after hearing Mr. Davis's and Mr. New's papers read at the last meeting, he had obtained two samples of gas from Blackfriars Street, and very carefully determined the amount of oxygen, finding 0·6 per cent. in each sample. If there were oxygen in the gas there must be air present, and there could not be a large quantity of nitrogen in the gas without there being a corresponding quantity of oxygen. Such a large percentage of nitrogen was very remarkable, especially from Salford gas, where it was very carefully made and where there would be no means of air rushing in without its being known. If they did pass air in they would only use just sufficient to revivify the purifiers, whether oxide of iron or lime were used; and with that end in view it would be folly to add more than four or five per cent. altogether, because half a per cent. of air could not possibly be taken up by partly fouled oxide. It might be said that they made a very good gas at Salford, and then reduced its illuminating power by passing air into it, but that would be a very expensive process, and if Mr. Davis's figures were correct, of which there could be scarcely any doubt, it would appear that a large quantity of air was being passed into the gas. Mr. Davis appeared to have found a large quantity of nitrogen in the morning. It was difficult to understand why there should be more in the morning than at night, for if they had to pass air in it would be in regular quantities, and it would be impossible to say into which holder it had passed.

MR. DUNCAN asked if the nitrogen might have got there by diffusion?

MR. CARPENTER said that he remembered it once being suggested that every gas manufacturer who proposed to put air in his gas should carefully measure it, but it was quite possible that air might get into the gas through cracked retorts.

MR. STENHOUSE: That would be an isolated case; whereas Mr. Davis had quoted many instances.

MR. CRIPPIN: I said that undoubtedly there were certain periods when gas contained large quantities of air, but how the air got there he could not say, unless it was through cracked retorts. He had just heard evidence given before a Parliamentary Committee with regard to the Eccles and Swinton districts which verified the fact.

MR. DAVIS, in reply, said that he could not see why it would be foolish to put air into gas, so long as the consumers were prepared to accept a mixture of gas and air. It was an undoubted fact that gas had a low illuminating power at certain times of the day; and it was also undoubted that the tests proved the presence of air, but whether it got there by diffusion through the pipes or joints as suggested, by Mr. Duncan, he was not prepared to say.

Meeting held Wednesday, 25th May 1892.

MR. L. ARCHBUTT IN THE CHAIR.

ON THE MANUFACTURE OF PORTLAND CEMENT FROM ALKALI WASTE AFTER TREATMENT BY THE CHANCE SULPHUR RECOVERY PROCESS.

BY CHARLES SPACKMAN.

THE accumulations of waste from the manufacture of soda by the Leblanc process have long been a source of unceasing trouble and expense to the manufacturers, and the proposal to make use of this waste as the lime constituent of Portland cement is not new. In a book on Portland cement by H. Reid, published in 1877, reference is made to experiments carried out at St. Helens some years previously with a view to its utilisation for this purpose, which were not successful, as the sulphate of lime interfered with the production of a perfectly hydraulic cement.

A paper describing his process for the manufacture of cement from alkali waste was read before the Liverpool Section of this Society by J. S. Rigby (this Journal, 7, 301), in which the author states that his attempts to produce cement with the unpurified waste were unsuccessful.

"It produced a cement of a very uncertain quality; when made into briquettes and placed in water they frequently crumbled away, or if they held together at all a very slight strain caused them to break. The cement had also an unpleasant slippery feel with it when taken from the water; it also evolved sulphuretted hydrogen when treated with an acid." Cement of good quality was, however, obtained by purifying the waste. This was said to be accomplished by passing carbon dioxide obtained from the calcination of a previous kiln of cement through the semi-liquid waste, either before or after it had been mixed with the required quantity of clay.

A second paper, by the same author (this Journal, 9, 254), considers the action of calcium sulphate on cement, and describes a continuous process of calcination.

In Mr. Chance's paper describing his sulphur recovery process, three analyses of the waste after treatment by this process are given (this Journal, 7, 162), and reference is made to the possibility of utilising it for the manufacture of cement. In this paper I propose to briefly consider this subject, and to give the result of an actual experiment.

The analysis of the waste with which my experiments were made was as follows:—

Coke	27.492
Sand	1.694
Silica	1.156
Alumina	0.926
Ferrous sulphate	1.488
Ferrous sulphide	0.421
Calcium carbonate	68.861
Calcium sulphate	4.735

	<u>100.277</u>

Sulphur compounds exist here in much larger quantity than in the samples of which analyses are given by Mr. Chance. The presence of sulphur to any great extent in the raw materials is liable to seriously interfere with the production of Portland cement of even moderate quality, and as the material in question will always certainly contain a small quantity, and may contain a considerable one, we must, as part of our subject, consider what its effects are, and to what extent its presence is detrimental.

The action of sulphates on lime was first investigated by the late General Scott, R.E., F.R.S., now more than 25 years ago. Experimenting with the Plymouth hydraulic limestones and burning a piece of the stone in a dull fire, he found on grinding to a fine powder and mixing with water that instead of slaking and heating as previous samples had done, it set and hardened in exactly the same manner as a cement. He consulted Dr. Faraday respecting this, and they came to the conclusion that the change was due to the formation of some form of sub-carbonate of lime. It was, however, subsequently ascertained that it was caused by the presence of a small quantity of calcium sulphate formed by the action of the iron pyrites of the

coal. This led to the invention of Scott's cement, which was made as follows:—grey chalk lime, such as that of Barham on the Medway, containing from 10 to 15 per cent. of clay, was reheated to redness in shallow kilns with perforated hearths. When the lime was sufficiently hot, pots of sulphur were placed beneath the hearths, the sulphur being immediately ignited by the heat of the kilns. The sulphur dioxide evolved combined with the lime to form calcium sulphite which afterwards passed to sulphate. When finely ground the cement was ready for use.

This system of manufacture was about 1871 abandoned for a much simpler one, the lime being finely ground with a certain proportion of gypsum. When so treated it is known as selenitic lime, and it is now manufactured in large quantities from the hydraulic limestones. Mortar made with selenitic lime hardens rapidly and possesses a much greater strength with a larger proportion of sand than if made in the ordinary manner with the same lime not made selenitic.

General Scott also found that by the addition while grinding of a quantity not exceeding 2 per cent. of gypsum to hot overlied Portland cement with a tendency to expand and blow, it could be rendered fit for immediate use without undergoing the usual process of air slaking, and that sound but quick setting cement could be rendered slow setting by the same treatment. This fact is now so well recognised that the German standard rules, which most stringently regulate the addition of any foreign substance to Portland cement by the manufacturer, allow gypsum to be added in quantity not exceeding 2 per cent. to confer slow setting properties. Its effects are well illustrated by the results given in the following table by Messrs. Dyckerhoff taken from the Minutes of Proceedings Inst. C.E., Vol. LXII, p. 92, which shows the gradual increase in the time of setting of a sample of quick-setting cement by the addition of $\frac{1}{2}$, 1, and 2 per cent. of gypsum, and the corresponding increase of strength, both neat and with three parts of standard sand at from one to fifty-two weeks:—

TABLE BY MESSRS. DYCKERHOFF.
Showing the increase in strength which results from an increase in the time occupied in setting.
Kilogrammes per sq. centimetre.

No. One Sort of Cement.	Time of Setting.	Neat Cement. 275 Grains of Water to 1,000 Grains of Cement.					One of Cement to Three of Sand. Standard Test.				
		Neat.	One Week.	Four Weeks.	Twelve Weeks.	Twenty-five Weeks.	One Week.	Four Weeks.	Twelve Weeks.	Twenty-six Weeks.	Fifty-two Weeks.
	Minutes.										
1	20	22.7	28.5	36.4	43.7	49.3	8.1	11.8	16.7	21.2	25.3
2 The same cement with $\frac{1}{2}$ per cent. of gypsum	240	22.2	32.1	40.3	43.9	45.8	10.0	14.9	23.8	24.8	27.4
3 The same cement with 1 per cent. of gypsum	600	26.4	35.7	39.9	49.0	51.9	11.2	16.7	21.9	25.9	27.0
4 The same cement with 2 per cent. of gypsum	840	29.9	38.2	48.4	50.5	50.7	12.7	18.5	21.4	26.3	28.8

We must now consider calcium sulphate occurring as one of the constituents of Portland cement, instead of being added after burning. The materials in general use for the manufacture, as a rule, contain sulphur compounds in such small quantity that practically their presence may be disregarded. At the same time, calcium sulphate occurs in more or less quantity in all Portland cement, its presence being due to the coke used as fuel. The sulphur dioxide evolved during its combustion, in passing upwards through the layers of unburned material in the kiln, to some extent attacks the calcium carbonate, forming ultimately calcium sulphate, as in the manufacture of Scott's cement, except that in the latter case entire absorption of the sulphur dioxide was secured by heating the lime to redness. The formation of calcium

sulphate is less in open than in closed kilns, and less in some forms of closed kilns than in others. The quantity, however, due to this cause is too small to, of itself, at all influence the character of the cement, but many French engineers attach great importance to the freedom of Portland cement from sulphuric acid—it is difficult to understand why—and specify a maximum percentage. The cement specification for the Boulogne harbour works contains a clause providing that sulphate of lime shall not exceed 1 per cent., a condition that few, if any, English cements, which are generally burned with gas-coke, could comply with.

If the raw materials, as in the case of the desulphurised alkali waste, contain sulphur in any form—for even under the most careful treatment we know that it must do so, as any ferrous sulphide present cannot be decomposed, and

as we shall presently see, the quantity of calcium sulphate that may be present in the cement is a limited one, the quantity of this due to the ash and iron pyrites of the coke becomes an important consideration, and it is necessary to know what the amount really is. In the following table I have arranged the results of some experiments which show this:—

TABLE A.

	Unburned Material.		Cement.
	CaSO ₄ Per Cent.	FeS ₂ Per Cent.	CaSO ₄ Per Cent.
1.			1.169
2.			1.562
3.			1.501
4.	0.231		1.579
5.			1.691
6.			1.334
7.	0.004		1.990

The mixture as dried ready for the kiln in Nos. 1 to 6 contains only 0.231 per cent. of CaSO₄, which would give about 0.32 per cent. in the cement. FeS₂, a common constituent of many clays, was entirely absent. The kilns were open ones of about 20 tons of cement capacity. About one-half the coke was gas-coke; the remainder was made in ovens underneath the drying flats. The cement from each of six kilns was ground separately and carefully sampled, the CaSO₄ being determined in each with the results given in the table. The average of these is 1.528, and if we deduct 0.32 per cent., the approximate quantity due to that originally present in the raw materials, we have 1.2 per cent. derived from the coke. Practically, the cement differed in no way from specially prepared samples in which the CaSO₄ fell considerably below 1 per cent.

In No. 7, the CaSO₄ in the material before burning exists as a mere trace, FeS₂ being absent. The cement was burned in closed kilns, with the result that we get 1.99 per cent. of CaSO₄ derived entirely from the coke.

In the next table the results show the CaSO₄ present in the cement produced by burning by different methods, a mixture containing sulphur present principally in FeS₂.

TABLE B.

	Unburned Material.		Cement.	How Burned.
	CaSO ₄ Per Cent.	FeS ₂ Per Cent.	CaSO ₄ Per Cent.	
1.			6.130	In 30-ton close kiln, with a head draught. Whole product of kiln.
2.			5.972	As No. 1.
3.			5.902	As No. 1.
4.			5.950	As No. 1, but a very sharp draught. A high wind during whole time kiln was burning.
5.	0.442	1.677	4.778	As No. 1, but draught of kiln permanently improved.
6.			4.148	As No. 1. Sample from bottom of a kiln.
7.			5.100	In open 30-ton kiln. Whole product.
8.			3.803	In open 20-ton kiln. Whole product.
9.			3.872	In open 15-ton kiln. Whole product.
10.			4.320	From top of 15-ton open kiln.
11.			3.349	From bottom of 15-ton open kiln.

A consideration of this table will show that it is not an unimportant matter in what state sulphur if present exists in the raw materials. Taking the example given, we find that the mixture before burning contained 1.677 per cent. of FeS₂. This quantity is equivalent to 3.801 CaSO₄, and would make with the 0.442 actually present as CaSO₄ a total of 4.243 before burning, giving in the cement about 6.33 per cent. of CaSO₄. If we take into account that derived from the coke, which, in a closed kiln of the kind used for burning cements Nos. 1 to 4, would certainly be not less than 2 per cent., we should get 8.3 per cent. of CaSO₄ in the cement, supposing the S present combined with Fe as FeS₂ had existed in combination with lime as CaSO₄, or if the SO₂ evolved by the decomposition of the FeS₂ had entirely combined with lime.

The presence of 8.3 per cent. of CaSO₄ would be fatal to the cement, and it will be noticed that it is much higher than any of the tabulated results. Evidently then a considerable amount of sulphur escaped from the kilns as SO₂, the best results being obtained in the small open kilns, there being practically no difference between those of 15 and 20 tons capacity.

The cements in Table B, with many others in which the CaSO₄ varied from 3 to 6 per cent., were tested against a sample containing only 2.5 per cent., and their behaviour carefully watched. The 2.5 per cent. sample was prepared in the same manner and from practically the same materials as the other cements, by omitting a shale which contained the principal part of the FeS₂ and substituting another containing a smaller quantity.

Generally, the results were as follows:—From 2.5 to about 4 per cent. of CaSO₄, both the time of setting and the comparative strength of all the samples tested increased with the percentage of CaSO₄, and all were moderately slow setting.

With from 4 to 6 per cent. of CaSO₄ all the cements did not give good results. Those that were successful set much more slowly than the previous series, the time occupied in setting increasing with the percentage of CaSO₄, until with 6 per cent. the cement set so slowly as to render it unsuitable for many purposes. The strength of these when tested without sand was very great at short periods of time, much greater than was the case with those containing below 4 per cent. of CaSO₄; with sand the results were not quite so good. All the test briquettes were moulded as soon as possible after the cement was ground, and in no case was any sample improved by exposure to air before being tested. It has been already explained that the effect of gypsum added in small quantity to quick-setting cement or to freshly-made cement with a tendency to expand or blow, is to render it slow setting and fit for immediate use without being air-slaked. We now see that the same effect is produced by CaSO₄ occurring as one of the constituents of the cement.

The tests, some thousands in number, extended over a long period of time, and the result generally showed a high initial strength steadily increasing with age, except, of course, in the case of the samples just mentioned as not having given good results, the cause of the failure of which we must now consider.

We have hitherto assumed that the whole of the sulphur present in the cement exists in CaSO₄, but this is not strictly true, as a small quantity of CaS is also always present, which is formed by the reduction of CaSO₄ during the calcination of the cement, which takes place in contact with the fuel. Even if only 1 per cent. of CaSO₄ is present, CaS will also be found, and the larger the quantity of CaSO₄ the larger is the quantity reduced to CaS. If ordinary care is exercised in the manufacture, the quantity of CaS in cements containing up to 4.5 per cent. of CaSO₄ is not a matter of great importance, but from 4.5 to 6 per cent. it may exist to so great an extent as to entirely ruin the cement.

I found that when the CaSO₄ would exceed 5 per cent. in the finished cement, great care was necessary during the process of manufacture to prevent the formation of a dangerous excess of CaS, to which cause the failures were due. Briefly, its effects are as follows:—The fine blue grey colour of the freshly-ground cement gradually changes to a

dirty brown. This is caused by the CaS in presence of the moisture of the air reacting with the FeO or Fe₂O₃ existing in the cement. FeS first forms, this slowly oxidises to FeSO₄, which is further oxidised and becomes brown. This reaction takes place much more rapidly when the cement is gauged. Samples left in air dry out a dirty brown colour, if broken when dry the fractured parts are of a pale greenish blue, which rapidly becomes brown on exposure. If immersed in water the samples do not harden well especially when mixed with sand, and become throughout of a dark green colour, which changes to brown on removal from the water and exposure to air. The cement sets extremely slowly, even with a moderate proportion of water, with excess of water it will scarcely set at all, especially at a low temperature. Briquettes made of neat cement will, if allowed to thoroughly harden before being put in water, frequently possess a fair tensile strength, but with sand the strength when compared with that of ordinary cement of average quality is very low indeed.

The results of the experiments of which I have given a brief summary led me to fix the absolute limit to which CaSO₄ may be present in Portland cement at 5 per cent. This is considered, not as added to a normal cement, but as derived from the fuel and the materials from which it is made, the relative proportions of basic and acid constituents in the mixture before burning being arranged with reference to the percentage of CaSO₄ ultimately present in the cement.

Although my experiments were made with other materials and with a different object, they are equally applicable to the present case, in which we are considering the application of a material to the same purpose, the only drawback to its successful use being the presence of sulphur compounds.

The analysis of the alkali waste previously given shows that even when mixed with sufficient clay to bring the calcium carbonate down to about 72 per cent. in the dry mixture, it would still contain calcium sulphate in such quantity as to largely exceed in the cement the limit I have laid down.

An experiment was, however, made in the following manner: The waste was dried and ground in the dry state with clay fairly free from calcium carbonate. The mixture was pugged with a small quantity of water, and was moulded into bricks, which were dried on a heated floor and afterwards burned with coke in a trial kiln. Mixtures were made with various proportions of the alkali waste and clay, the cement in each case being ground and tested separately, with the result that every one of the samples failed, although some remained sound until put in water. Clearly then, it was necessary to devise some means of reducing the quantity of calcium sulphate if success was to be achieved, and the following method was adopted.

A marly clay was used containing from 30 to 40 per cent. of carbonate of lime. This rendered necessary the addition of a larger quantity than was used in the first experiments, and advantage was taken of the sparing solubility of calcium sulphate in water.

The materials were mixed in the wet way, using a considerable quantity of water, and the mixture was allowed to settle for some days in tanks, when the water was, as far as possible, drained from the surface of the deposited slip. This now contained about 66 per cent. of water, and, after being again thoroughly mixed by stirring, was allowed to run upon a drying flat heated by coke ovens, the floor being constructed of fireclay slabs. These absorbed a considerable amount of water from the slip, which, of course, together with that previously drained from the surface, was saturated with calcium sulphate. The process is really the one originally adopted for the manufacture of Portland cement from chalk and clay which is still largely in use, and which is fully described in a paper by myself (this Journal, 7, 102). In this case, however, a larger quantity of water was used, and the slip, instead of being allowed to settle for from six to eight weeks in backs until the water is reduced to 40 or 50 per cent., was, as time was of importance, run upon the drying flats in a more liquid condition.

In the following table of analyses, No. 1 is that of one sample of the dry slip prepared from the alkali mud and clay. The other two are for comparison with it. No. 2 is that of ordinary Portland slip or slurry prepared from grey chalk and gault clay. No. 3, the same material from white chalk and a pit clay.

	No. 1.	No. 2.	No. 3.

	100'200	99'348	98'763

The dried slip was burned in a trial kiln with gas coke. The previous experiments had shown that the mixture was very fusible, and great care was necessary to prevent over-burning. No attempt was made to get good results by selecting the best clinker for grinding. The under-burned material was first picked out, as is the usual practice, and the remaining contents of several kilns were ground together.

The cement set slowly (in about 10 hours) and was tested immediately after being ground. The briquettes were made in Graut's form of mould 1-inch section, were put in water 24 hours after moulding and left there until the moment of testing. They were tested in a Michéle's machine, strain being applied at the rate of 400 lb. per minute, with the following results in pounds per sq. inch.

	Neat Cement. Water 16·3 per Cent.			1 Cement, 3 Standard Sand, Water 5·2 per Cent.		
	Highest.	Lowest.	Average of 6 Tests.	Highest.	Lowest.	Average of 6 Tests.
At 3 days	620	570	588	200	185	192
At 7 days	640	600	615	200	170	190
At 28 days	770	712	746	350	300	317

For comparison with the foregoing tests, those following are given. They are of six samples of ordinary commercial Portland cement taken without selection from a register of tests.

	Neat Cement.			1 Cement, 3 Standard Sand.	
	3 days.	7 days.	28 days.	7 days.	28 days.
Cement A..	416	595	697	126	162
Cement B..	386	436	581	199	241
Cement C..	..	615	625	195	212
Cement D..	..	563	436	..	160
Cement E..	..	566	545	..	307
Cement F..	..	478	549	138	182

It will be noticed that the cement made from the alkali waste far exceeds any of these in strength, both neat and with sand. This is to some extent due to the calcium sulphate, but principally to the extremely fine state of division of the calcium carbonate, which rendered possible a most intimate mixture with the clay before burning, a result not always obtained when dealing with some of the natural carbonates except at a great, and often a prohibitive cost.

In comparing these results it is but fair to remember that the tests with sand of all of those in the second table would have been much higher had the cement been more finely ground, but the strength neat, in which condition, however, cement is rarely used would have been rather less. Any of these cements, some of which possess far less strength than that made from the alkali waste would, for many purposes, be much more suitable as they all set more quickly.

In the following table the analysis of four cements are given. No. 1 is that made from the alkali waste, the others are three samples of ordinary commercial Portland of very good quality. It will be observed that Nos. 2 and 3 agree fairly closely in composition with No. 1, but it must at the same time be remembered that the analysis of a cement taken by itself is no guarantee of its quality:—

	1.	2.	3.	4.
Insoluble residue.....	2.749	3.302	2.815	1.642
Silica.....	18.215	19.156	20.264	21.366
Alumina.....	8.948	7.136	7.306	8.826
Ferrie oxide.....	6.563	4.678	6.894	4.304
Lime.....	56.682	56.170	56.905	60.672
Sulphate of lime.....	5.006	4.778	3.389	1.507
Magnesia.....	1.639	3.101	0.963	1.116
Potash.....	0.654	1.327	1.102	0.789
Soda.....	0.779	0.440	0.375	0.289
	100.335	100.115	100.013	100.551

The results of my experiments show, that if so far free from sulphur compounds as to give in the cement calcium sulphate in quantity not exceeding 5 per cent., alkali waste may, after treatment by the Chance process for the recovery of its sulphur, be successfully utilised for the manufacture of Portland cement. With this quantity, however, the cement would set very slowly, but it could be made to set more quickly, and would be more generally useful if the calcium sulphate was reduced to from 3 to 4 per cent.

This material may be easily dealt with by the methods generally adopted for the manufacture of Portland cement from chalk and clay, but Tables A. and B. show that as regards kilns, open ones of moderate capacity are the most suitable as the quantity of calcium sulphate in the cement, derived from the coke and the sulphides present will be materially reduced by their use.

The following have been elected to fill the vacancies and will take office in July next: *Chairman*: C. A. Fawcitt. *Vice-Chairman*: E. J. Mills. *Hon. Secretary and Treasurer*: J. Stanley Muir. *Committee*: G. Beilby, W. J. Chrystal, J. S. Macarthur, T. L. Patterson, E. C. C. Stanford, and G. Watson.

Meeting held in the Societies' Rooms, 207, Bath Street, Glasgow, on Tuesday, 7th June 1892.

MR. E. C. C. STANFORD IN THE CHAIR.

NEW METHODS OF ESTIMATING CHROMIUM IN FERRO-CHROMIUM AND STEEL.

BY JOHN CLARK, F.R.S.

FERRO-CHROMIUM.

ON account of its technical importance, the estimation of chromium in ferro-chromium has engaged the attention of a considerable number of chemists, but the processes hitherto published are for the most part very tedious. This is to a large extent due to the difficulty which is experienced in getting the whole of the chromium into solution, as alloys rich in chromium are only partially soluble in nitric, sulphuric, or hydrochloric acids, or even aqua regia.

H. N. Warner, it is true (Chem. News, 65, 186), states that ferro-chromium is readily dissolved by heating with strong sulphuric acid, but I have not succeeded in completely dissolving in this way the alloys which I have had occasion to test, the best result obtained after heating with H_2SO_4 for a day giving 8.9 per cent. of insoluble chromium, and as they frequently contain aluminium his method of estimating the chromium by weighing the precipitates of oxide chromium and iron, and deducting the iron is, in my opinion scarcely entitled to be called accurate. According to R. Schöfel (Ber. Deutsch. Chem. 1879, 1863) even direct fusion with carbonate of soda and nitrate of potash is of no use, and he therefore recommends that the greater portion of the iron of the ferro-chromium should be dissolved out with the double chloride of copper and sodium or ammonium, and the residue fused with carbonate of soda and nitrate of potash, but he admits that this process is not suitable for alloys containing more than 8 per cent. of chromium.

A. Ziegler states that ferro-chromium can be dissolved by fusion with a large excess of bisulphate of potash or soda, but he recommends (Dingl. 279, 163) that the ferro-chromium should be fused with a mixture of 6 parts of caustic soda and 3 of nitrate of potash, and the chromium in the solution twice precipitated with ammonia after evaporation to dryness with hydrochloric acid to render the silica insoluble. In addition to this, the insoluble in water is dissolved in hydrochloric acid, and the oxide of iron tested for chromium.

In 1871 (Chem. News, 24, 286 and 301) I published a new method of estimating chromium in chrome iron ore, depending on the oxidation of the chromium by means of a mixture of caustic soda and magnesia, and subsequent titration of the chromic acid. In 1877, or fully five years afterwards, this process was reproduced by A. Christmann as his own in a paper read before the German Chemical Society (Ber. Deutsch Chem. 10, 16). I did not observe this publication at the time and would have taken no notice of it now, but I find that in Roseoc and Schorlemmer's Treatise on Chemistry (Vol. 2, Part 2, p. 183), Christmann's is referred to in a foot-note as the author of the process, and I therefore take this opportunity of pointing out my claim to priority. This process is very suitable for ores or oxide of iron precipitates, as the oxide of chromium is readily converted into chromic acid at the temperature of a Bunsen flame, but on applying it to poor ferro-chromium under the same conditions so little oxidation took place that I concluded it was necessary to oxidise the chromium before it could be converted into chromic acid by soda and magnesia. Unfortunately, ferro-chromium is only partially oxidised in the muffle or over a blowpipe, and even when heated in pure oxygen by means of a gas combustion furnace oxidation takes place very slowly. I found, however, on repeating my experiments with rich alloys of chromium, that when the temperature was lowered to a point at which it seemed scarcely possible that any action could take place the ferro-chromium, even when in coarse powder, was readily and rapidly oxidised by the soda and magnesia without the use of an oxidising agent such as chlorate or nitrate of potash, any excess of which would interfere with the subsequent titration of the chromium.

Magnesia and Soda Process.—One gram. of the finely pulverised ferro-chromium is intimately mixed in a platinum crucible with 5 grms. of magnesia mixture, consisting of two parts of freshly calcined magnesia, and three parts of finely pulverised hydrate of sodium, and the crucible is placed over a low Bunsen flame in such a manner that only the point of the flame touches the bottom of the crucible. Oxidation begins almost immediately, and takes place so rapidly that the contents of the crucible actually glow for several minutes. After heating at this temperature for about half an hour without stirring, the flame is raised and the bottom of the crucible maintained at a dull red heat for another half hour. The contents, which consist of an adherent powder, are then washed into a porcelain basin and boiled for some minutes to dissolve out the chromate, which is either pure yellow or slightly green in colour if manganese is present. To decompose the manganate peroxide of hydrogen is added drop by drop till there is no further change of colour, and after boiling for a few minutes to remove any excess of peroxide of hydrogen the solution is filtered, acidified with sulphuric acid, and the chromium estimated by adding an excess of ferrous ammonium sulphate, and titrating the unoxidised iron with a standard solution of bichromate of potash. Although the bulk of the chromium is rendered soluble in the first fusion, a little always escapes oxidation. To extract this the insoluble on the filter is ignited, ground in an agate mortar, and again fused with about twice its bulk of magnesia mixture for about half an hour, and the chromic acid is estimated as before. The insoluble is now washed into a beaker or basin, and the bulk of the magnesia is removed by adding dilute sulphuric acid till the reaction is neutral. The oxide of iron is then filtered off and again fused with magnesia mixture, when the last traces of chromium will be obtained.

Example.

	Found.	Per Cent.
	Grm.	
1st fusion.....	0.5491	54.91
2nd fusion.....	0.0320	3.20
3rd fusion.....	0.0096	0.96
4th fusion.....
Total.....	0.5907	59.07

Lime and Soda Process.—Rich ferro-chromium can also be oxidised by heating the finely pulverised alloy in the manner already described with five times its weight of lime (CaO) and sodium hydrate in equal proportion. In this case it is advisable before filtering to add about 2 grms. of bicarbonate of sodium to convert the lime into carbonate, but in other respects the process is the same. As a rule, however, at least four fusions are needed to extract the whole of the chromium.

Calcium Hydrate Process.—Although alloys of chromium are difficult to oxidise when heated alone either in air or oxygen, they are readily converted into oxide at high temperatures in presence of calcium hydrate, and this fact can be utilised for the estimation of the chromium as follows:—

One gram. of the finely pulverised ferro-chromium is mixed with three times its weight of calcium hydrate and heated in a platinum, nickel or porcelain crucible in a muffle or over the blow-pipe for about half an hour when oxidation is practically complete. The action takes place most rapidly in platinum or nickel, but the platinum is strongly acted upon, and the nickel usually gives way after being used two or three times. It is therefore more economical to use a porcelain vessel. The contents of the crucible consist of a green powder, which can easily be crushed with a glass rod and contains no chromate. The oxide of chromium thus formed may be converted into chromic acid by adding to the crucible 5 grms. of the magnesia and soda mixture above referred to, stirring with a rod and heating in the muffle or over a Bunsen for about an hour; but when the ferro-chromium is employed in coarse powder it is advisable to grind the lime fusion before the addition of the magnesia mixture. The contents of the crucible, which seem to have little or no action on the porcelain, are boiled with water and a little peroxide of hydrogen, filtered after the addition of about 3 grms. of bicarbonate of sodium, and the chromic acid titrated in the manner already described. As a small quantity of the chromium usually escapes oxidation, the insoluble is again heated with about its own bulk of the magnesia and soda mixture for about half an hour, and the chromate estimated as before. The insoluble should now be neutralised with dilute hydrochloric acid to remove the bulk of the lime and magnesia, and the residue subjected to a third fusion to ensure the extraction of the last trace of chromium.

Example.

	Nickel Crucible.		Porcelain Crucible.	
	Found.	Per Cent.	Found.	Per Cent.
	Grm.		Grm.	
1st fusion.....	0.5645	56.45	0.4994	49.94
2nd fusion.....	0.2321	2.31	0.0673	6.73

4th fusion.....	0.0025	0.25
Total.....	0.5921	59.21	0.5925	59.25

This process works well, and is more suitable for poor alloys of chromium than those which I have already described.

The oxide of chromium produced by heating 1 grm. of the ferro-chromium with hydrate of calcium may also be converted into chromic acid by heating with 4 grms. of carbonate of soda in the muffle, but, as a rule, a smaller yield of chromate is obtained in the first fusion and more fusions are required. In other respects the process is the same and the results equally correct.

Example.

	Cr Found.	Cr Per Cent.

5th fusion.....	0'0020	0'20
Total.....	0'5895	58'95

Sulphur Process.—The disintegration and oxidation of ferro-chromium can also be effected by means of sulphur instead of hydrate of calcium. For this purpose 1 grm. of the finely pulverised alloy is placed in a porcelain boat and subjected for about 30 minutes to the action of sulphur vapour in a porcelain tube heated by an ordinary gas combustion furnace. As soon as the vapour comes in contact with the heated ferro-chromium a strong action takes place, the metal glows and swells up to several times its original bulk, and a little powder is apt to be carried away mechanically by the sulphur vapour and scintillates. The product, which is greyish black in colour, is in the form of a fine powder and consists essentially of Cr_2S_3 and FeS . The sulphide thus produced is easily ground in an agate mortar, and may be at once converted into chromate by heating over a Bunsen with eight times its weight of the magnesia and soda mixture already referred to, or it may be converted into oxide by ignition in a porcelain crucible, then fused with five times its weight of the mixture, and the chromic acid titrated as already described after removing the manganese.

Example.

	(A.)		(B.)	
	Cr Found.	Cr Per Cent.	Cr Found.	Cr Per Cent.
	Grm.		Grm.	
1st fusion.....	0'5606	56'06	0'5713	57'13
2nd fusion.....	0'0229	2'29	0'0075	0'75
3rd fusion.....	0'0015	0'15	0'0029	0'29
4th fusion.....
Total.....	0'5850	58'50	0'5817	58'17

The results obtained by this method are rather lower than by the other processes, but this is in my opinion sufficiently accounted for by the slight mechanical loss sustained.

The ferro-chromium may also be completely converted into sulphide by heating with excess of sulphur in a covered porcelain crucible over a Bunsen, but in this case it is necessary to repeat the operation three times, as the action takes place chiefly when the bulk of the sulphur has been volatilised, and the scintillation and mechanical loss are greater.

Carbon Bisulphide Process.—Sulphurisation can also be effected by exposing the metal to the action of carbon bisulphide vapour in a porcelain tube heated by a combustion furnace. The product in this case also is a bulky

powder, a portion of which is apt to fall over the side of the boat, but otherwise there is apparently no mechanical loss. It requires no grinding, and is heated with magnesia and sodium hydrate either with or without previous roasting, and the chromium estimated as described. One grm. ferro-chromium gave with this treatment:—

STEEL.

On account of its greater solubility in acids, the estimation of chromium in steel is usually considered to be easier than in ferro-chromium, but I must confess it has given me more trouble. I have already indicated that poor alloys of chromium are very imperfectly oxidised when heated direct with sodium hydrate mixed with magnesia or lime, and the same holds good to a still greater extent with steel. Calcium hydrate works better, but the oxidation of the chromium seems to be prevented by the formation of a crust of oxide of iron; and when this method is used it is necessary to grind the lime fusion once or twice to expose a fresh surface. When this is done, fairly good results are obtained, but the sulphur and carbon bisulphide processes are by far the best. When steel turnings are exposed to the action of sulphur vapour, there is no indication of mechanical loss as in ferro-chromium, and the sulphide produced appears slightly fused. Sometimes it adheres to the porcelain, but it can generally be detached, in which case it is pulverised, then roasted in a porcelain crucible, and fused with four times its weight of the mixture of magnesia and sodium hydrate already referred to, and the chromium estimated as described.

When the sulphide adheres firmly to the porcelain, it is ignited in the boat itself till it can be detached and ground. Two fusions are generally sufficient for the extraction of the whole of the chromium.

Example.

Three grms. of a steel received from Mr. R. A. Hadfield, of the Hecla Works, Sheffield, and said to contain 1'60 per cent. of chromium, gave the following results by this process:—

	(A.)		(B.)	
	Cr Found.	Cr Per Cent.	Cr Found.	Cr Per Cent.
	Grm.		Grm.	
1st fusion.....	0'0480	1'60	0'0492	1'64
2nd fusion.....	0'0036	0'12	0'0024	0'07
3rd fusion.....
Total.....	0'0516	1'72	0'0513	1'71

Although the sulphur process works well, the carbon bisulphide method is, in my opinion, the best for steel. It is most conveniently carried out by attaching a flask containing carbon bisulphide to one end of the porcelain tube and a small condenser to the other, and passing a gentle stream of CS_2 vapour over the heated steel for about an hour. On the removal of the boat, it will be observed that the steel drillings have increased considerably in bulk and are soft and porous, but they retain their original form. As the product has no tendency to adhere to the porcelain,

it can at once be transferred to a crucible and roasted. Oxidation takes place very rapidly, and in the course of about half an hour the sulphide is converted into a fine powder without stirring or grinding, and may be at once heated with four times its weight of the mixture of magnesia and sodium hydrate, and the chromate extracted and estimated as described.

Example.

Two grms. of the steel from the Hecla Works treated in this way—

	Cr Found.	Cr Per Cent.
	Grm.	
1st fusion	0.0332	1.66
2nd fusion	0.0018	0.09
3rd fusion
Total	0.0350	1.75

These methods involve several fusions, but the time occupied in the estimation of the chromium should not exceed one day, and, of course, the filtrates from the different fusions can be united and titrated as one.

for a little while and then stopped by closing clip *x*. Some water is now poured into flask *R* and boiled down to expel all the air from the apparatus. At first clips *g* and *m* are open and clips *x* and *w* closed. After some time *m* is closed and the steam allowed to go out through *w*. When the water in flask *R* has been boiled down to about 5 or 10 cc. *w* is closed and the lamp withdrawn. Clip *e* is then closed and clip *x* is opened cautiously so as to prevent the water rushing too quickly into the collecting cylinder *S*. Clip *x* is now kept open to the end of the experiment. Any remaining air bells in *S* are forced out through *m*, and it is then connected with a Schiff's nitrogen measurer charged with mercury. *R* is then charged with 500 cc. of the water under analysis by means of the funnel and capillary delivery tube *i*, and the tube filled with mercury to prevent any gas lodging in it. The extraction is now carried out as usual. After the gases have been collected in *S* they are transferred to the Schiff and in many cases the analysis completed there.

The advantages of the apparatus over Jacobsen's are obvious, for both the troublesome process of sealing up the tube, and the still more troublesome operation of transferring the gas to an apparatus for its analysis are obviated, and also it is easy to test and find if all the gases are expelled.

A series of test analyses with the apparatus described gave very satisfactory results.

ON MAIZE OIL.

BY J. CRICKSBANK SMITH, B.S.C.

MODIFICATION OF KREUSLER'S NITRIC ACID APPARATUS FOR THE EXTRACTION OF DISSOLVED GASES IN WATER.

BY JAS. ROBSON.

Chief Assistant to the "Freeland" Professor of Chemistry in the Glasgow and West of Scotland Technical College.

SOME time ago, at the suggestion of the late Professor Dittmar, I carried out a number of experiments to see if Kreusler's apparatus could be adapted for the extraction of the dissolved gases in water. The first series of experiments was made with a combination of Jacobsen's and Kreusler's apparatus. Instead of Kreusler's nitrate flask I inserted a Florence flask and pear-shaped bulb. This method I found did not work well, as the pear-shaped bulb was liable to collapse when being pushed further into the Florence flask so as to establish communication between them.

The second series of experiments was carried out with the apparatus shown in the figure. The method of working the apparatus is as follows:—The bolt-head *T* is filled with

THE grain of the maize plant (*Zea Mais*), which is extensively used in the manufacture of starch, can be made to furnish an oil whose properties would seem to render it suitable for several technical applications. At the suggestion of Professor E. J. Mills, I have recently examined a sample of this oil which is believed to be genuine, and the results have been embodied in the present paper.

The sample was of a bright golden colour, it had a somewhat peculiar "starchy" odour, and its taste was mild and not unpleasant.

Specific Gravity, &c.—At different temperatures the specific gravity was as follows:—

At 10° C.	0.9267
At 15° C.	0.9244
At 20° C.	0.9218

The mean coefficient of expansion (corrected for glass) between 10° and 20° C. was 0.000706.

Schaeidler (Technologie der Fette und Oele) gives the specific gravity at 15° as 0.9215, and Professor Mills informs me that in 1884 he found a rather coarse brown sample to have a specific gravity of 0.9262.

At -10°, according to Schaeidler, the oil sets to a solid mass. I find, however, that when exposed to intense cold, the oil becomes turbid, owing to the deposition of solid matter at -10°, and that below that temperature it becomes very viscous, but is still fluid at -20°. The precipitated solid matter is entirely redissolved on warming up again.

Bromine and Iodine Absorptions.—These were as follows:—

	Per Cent.
Bromine absorption	66.50
Iodine absorption	122.90
Iodine absorption (calculated: Br absorption $\times \frac{127}{80}$)	165.50

It was observed that when the bromine solution remained in contact with the oil for more than 15 minutes, the results obtained were somewhat higher, and did not agree among themselves, owing, no doubt, to a secondary oxidising action.

from 2 to 3 litres of boiled-out hot distilled water, which is kept about boiling to the end of the experiment. The siphon *n z* is filled by blowing in at *s* and allowed to run

A thick dark-coloured sample was found by Professor Mills in 1881 to have a bromine absorption of 74.42 per cent.

Saponification and Action of Alkalis.—On saponification with alcoholic potash, the total KOH absorbed was 19.34 per cent., which gives a "saponification equivalent" of 290.07.

The free acid, estimated directly by titration with N_{10} soda, amounted to 0.55 per cent. in terms of KOH. On performing a cheek experiment, however, by placing in contact with the oil a measured excess of alkali of known strength, in presence of a little alcohol, and titrating back with standard acid, I found a much greater proportion of alkali absorbed, and examination showed this to be due to partial saponification. In order to determine how far saponification could proceed with this oil in the cold, the following experiments were carried out:—Solutions of caustic potash and soda in alcohol were prepared separately, the proportion of alkali to solvent being $5\frac{1}{2}$ per cent. in each case. Small quantities of the oil (1 to 2 grms.) were then placed in contact with a considerable excess of each of the solutions for four hours at the ordinary temperature. After that time it was found that the oil in the potash solution was completely saponified, 19.3 per cent. of KOH being absorbed, and a perfectly clear solution being obtained. On the other hand, the oil in the soda solution was only partially saponified, 10.36 per cent. of NaOH being absorbed, which is equivalent to 14.50 per cent. of KOH. In the latter case a pasty mass of soda soap, insoluble in the alcoholic solution, formed after a short time, and this may have had a retarding effect on the rate of saponification.

It was at first thought that this ready saponification in the cold might be made use of for the quantitative separation of maize oil from other oils; but while no other oil that I have examined gives such a high absorption in the cold as maize oil, many of them are undoubtedly acted upon under similar conditions, and concordant results could not be obtained.

The higher fatty acids present in maize oil seem to present no unusual features, but exact determinations as regards the proportion in which they are severally present were not made in the present instance.

The volatile fatty acids, separated by Reichert's distillation process, in 100 parts of the oil required for their neutralisation 0.56 parts of KOH.

Drying properties.—A tendency to oxidise or to gum is almost absent in this oil. No decided siccativ properties are communicated to it by simple "boiling," or by the addition of litharge to it. On passing a current of air through it for an hour at a temperature of about 150°C ., the oil becomes slightly darker in colour, and rather more viscous, but by no means to the same extent as cotton oil. If to the oil so treated a small quantity of borate of manganese is added, the oil acquires to a small extent siccativ properties, and a thin film on lead dries in from 10 to 20 hours, but not completely, being tacky to the feel at the end of that time. Like cotton-seed oil the elaidin reaction gives rise to a mass having a pasty or buttery consistency.

Maumené test.—The rise in temperature when 5 cc. of strong sulphuric acid were mixed with 15 grms. of the oil was 89.0°C . For a non-drying oil this is a high figure, but it is in keeping with what may be called the "tenderness" of this oil in the presence of chemical reagents. The so-called qualitative tests for oils with sulphuric and nitric acid, &c., fail to give with maize oil reactions sufficiently characteristic to warrant their application in identifying or detecting this oil. Hence its bromine and iodine absorptions, its high Maumené figure, and the ease with which it saponifies in the cold, must be looked upon as the features by which the oil may be best recognised.

Technical applications.—Specimens of the potash and soda soaps were prepared, and both of these proved to be of good quality, being light in colour, and readily and completely soluble in water. The soda soap is distinctly

the harder of the two, but the potash soap is harder than the average "soft" soaps. Soap-making, therefore, is a use to which the oil might with advantage be put. The ease with which it saponifies, also, might make it useful to mix with other oils to accelerate their saponification. As a lubricant it might in certain cases be applicable, its low acidity, and its small tendency to deposit solid matter or to "gum," being properties that recommend it for this purpose.

The oil dissolves readily in acetone and more sparingly in alcohol or glacial acetic acid.

The following numbers represent the volume of oil dissolved by 100 vols. of the three above-mentioned solvents.

Solubility.—In 100 parts (by vol.) of—

Absolute Alcohol $t = 16^{\circ}\text{C}$.	Absolute Alcohol $t = 63^{\circ}\text{C}$.	Commercial Acetone $t = 16^{\circ}\text{C}$.	Glacial Acetic Acid $t = 16^{\circ}\text{C}$.	Glacial Acetic Acid $t = 63^{\circ}\text{C}$.
2	13	24	3	9

Viscosity.—This was determined roughly by observing the time of flow of 5 cc. of the oil through a burette with a capillary point, and comparing the results with standard oils.

$t = 18^{\circ}$ to 19°C .

—	Maize.	Olive.	Colza.	Mineral "910."
Specific gravity.	0.924	0.918	0.915	0.910
Time of flow....	177.3"	214.5"	290.0"	243.5"
Viscosity.....	61.1	84.3	100	83.9
(Colza = 100)				
do. (water=1)	25.7	35.4	42.0	35.2

Maize oil thus possesses a striking individuality. In general it may be said that in properties it is somewhat akin to cotton-seed oil. At the same time there are differences between them which are very marked.

DISCUSSION.

The CHAIRMAN said that he gathered from the paper that castor oil was the nearest approach to this maize oil, and although it did not resemble it in appearance it did so by being soluble in alcohol. He wondered whether there were any particular acids present. He noticed too, that the potash soap was quite solid.

Dr. CLARK asked whether the sample of oil was obtained from the germ or from the whole maize.

Mr. SMITH, in reply to the Chairman, said that the exact determination of the acids had not been undertaken. Regarding the source of this sample of oil he could not give any particulars, but it seemed different from the sample which Professor Mills had some years ago. It, he supposed, was derived from the germ.

"BLOWN" OILS.

BY R. T. THOMSON AND H. BALLANTYNE.

The published analytical data of any value in the chemical examination of "blown" oils are very few, and indeed extend only to two or three isolated facts. About six years ago Messrs. Fox and Baynes showed that the percentage of insoluble fatty acids in rape oil was reduced to 85.5 per cent., and those in cotton-seed oil to 81.7 per cent., when these oils were oxidised by blowing air through them, at a temperature of 70 to 75 °C., until they reached a specific gravity near that of castor oil. Allen, in his second volume on "Commercial Organic Analysis," showed that the alkali-neutralising power of blown rape oil was considerably higher than that of the original unoxidised oils. Taken in conjunction with their high specific gravity, these are the main facts known, or at least published with regard to blown oils. In the following paper we have endeavoured to throw a little more light on the composition of these oils, in order that their detection and differentiation may be effected with somewhat more certainty than has been before possible. As our time has been limited we have confined our observations to blown rape, cotton-seed, and sperm oils; and the results of the experiments are embodied in the accompanying table.

The first three columns contain the results of experiments on rape oil at different stages of oxidation. After analysing the pure rape oil about 50 cc. of it were placed in a tall narrow glass, provided with a cork, through which passed two glass tubes, one above the level of the liquid and the other reaching to the bottom of the glass. The latter had a few minute perforations at the lower end to allow the passage of air in a finely divided form through the oil. The shorter glass tube was now connected with a suction pump, by means of which a rapid stream of air was drawn through the oil. During the passage of the air the vessel containing the oil was immersed in a large beaker of water maintained at a temperature of 72 to 75°. After five hours treatment the product, as shown in the second column, had increased in specific gravity and alkali-neutralising power, and decreased markedly in iodine absorption. After "blowing" for 20 hours the specific gravity of the oil had risen from 914.1 to 964.5, which is about the average gravity of castor oil. It is interesting to observe that the free acidity had at the same time increased about 2 per cent., and the potash-neutralising power more than 2 per cent.; while the iodine absorption had fallen more than 37 per cent. This loss of power to

absorb iodine appears to be directly due to the absorption of oxygen during the "blowing" with air, and the further the oxidation is carried the lower will the iodine absorption become. The increase in free fatty acid points to the fact of decomposition of the oil, but that it is no true measure of the extent of decomposition will be seen by a reference to the partial analysis of the oil next given in the table. While the pure rape oil contained 94.76 per cent. of insoluble fatty acids, the "blown" product contained only 85.94 per cent. of insoluble acids, with an additional 9.2 per cent. of soluble non-volatile acids, and 0.82 of soluble volatile acids. These results were arrived at by saponifying the oil with alcoholic potash, evaporating off the alcohol, dissolving in water, and liberating the insoluble acids with sulphuric acid. These were collected, washed with hot water, dried, weighed in the usual way, dissolved in alcohol, and their molecular weight determined by titration with standard alcoholic potash, using phenolphthalein as indicator. The filtrate was then distilled to dryness, the distillate neutralised with standard barium hydrate, the solution evaporated to dryness, the barium salt weighed, then converted into barium sulphate, and from these data the molecular weight and proportion of the soluble volatile acids were calculated. The soluble non-volatile acids were extracted by ether from the dry residue left after distilling off the volatile acids, weighed after expelling the ether, and their molecular weight determined by standard alcoholic potash.

With these facts before us it is scarcely necessary to point out how they can be utilised in the detection and estimation of blown rape oil in other oils. With regard to the molecular weight of the insoluble acids it may be mentioned that Messrs. Fox and Baynes state it to be 186, while our result shows 327. The first figure seems to us to be quite inconsistent with the alkali-neutralising power of the oil as given by Allen, and determined by ourselves.

In the fourth column of the table are given the results of an analysis of a commercial sample of blown rape oil, which confirm those just described. This sample, however, contains a somewhat large proportion of unsaponifiable matter, probably derived from some fish oil adulterant in the original rape oil.

The fifth column of the table contains the results of an analysis of commercial blown cotton-seed oil, and a similar change in constitution is observable by blowing with air as in rape oil. It will be noticed, however, that the molecular weight of the soluble volatile acids contained in blown cotton-seed oil is much higher than that of the product from rape oil. The true means of distinguishing them is

to be found in the large difference in alkali-neutralising power, as all the other data approach too close to each other to provide any means of determining which oil is being tested. In making these comparisons it is apparent that the oils must have reached the same state of oxidation before correct deductions can be made. Thus, a blown rape oil of a specific gravity of about 960 ought to be compared with a blown cotton-seed oil of about 968.

The only other point to which special reference may be made is the largely increased power of developing heat when mixed with sulphuric acid, possessed by the blown over the unblown rape and cotton-seed oils. This is expressed as the specific temperature reaction, for the definition of which term, and method of determination, see our paper in this Journal for 1891, page 233. The increase in specific temperature reaction by oxidation of oils exposed to air and light has already been shown by one of ourselves (see "The Effect of Exposure under certain Conditions upon some Constants of Oils," by H. Ballantyne, in this Journal for 1891, page 29).

In the sixth and seventh columns of the table are recorded results obtained in the analysis of pure sperm oil, and the same oil after treatment for 25 hours with air in the same apparatus as was used in blowing the rape oil. Of course blown sperm oil is not an article of commerce, but it occurred to us that it might be at least interesting to observe the effect of oxidation on an oil having a totally different chemical constitution to that of rape or cotton-seed oil. It will be observed that the increase in specific gravity is not nearly so great with sperm as with rape oil, for while 25 hours treatment raised the specific gravity of the sperm oil 19 units, a treatment extending only to 20 hours sufficed to raise the specific gravity of the rape oil 47.4 units. This plainly shows that rape oil is more easily oxidised than sperm oil, a fact which almost goes without saying when their comparative qualities as lubricants are taken into account. These observations are corroborated by the iodine absorptions, which were reduced 15 per cent. only in the case of sperm oil, and 37.3 per cent. in that of rape oil. Thus, although these oils differ so entirely as regards their source and chemical constitution, yet their specific gravity and power of absorbing iodine rises and falls in almost exactly the same ratio during oxidation by air-blowing. If we assume that the change is regular from one extreme to the other, the fact is established that a unit of rise in specific gravity is equal to a decrease of 0.787 per cent. of iodine absorption in the case of sperm, and of 0.789 in that of rape oil. Another noticeable fact is the increase in free fatty acids, in which sperm agrees with rape oil, and which may be regarded as an invariable accompaniment of the prolonged oxidation of oils. Lastly, there is a fall in the proportion of unsaponifiable matters to the extent of 1.67 per cent., a circumstance which is not at all surprising, as these alcohols may be in part oxidised to acids during the blowing, and thus be lost in the subsequent saponification.

DISCUSSION.

The CHAIRMAN said that Mr. Thomson had gone into the subject with quite his usual minuteness. The experiment on sperm oil seemed to him to be remarkable.

Dr. CLARK said that Mr. Thomson had referred to the fact that experiments with oil blown on the large scale differed from those made on oil blown in the laboratory. Would this not be due to the fact that on the large scale a higher temperature was maintained while blowing the oil?

Mr. PATTISON asked if Mr. Thomson noticed any increase in the weight, or if there was any product driven off during blowing.

Mr. THOMSON, in reply to Dr. Clark, said, the only difference referred to was the difference in the unsaponifiable matter. With regard to the increase in weight mentioned by Mr. Pattison, they had that point in mind, but had not had time to investigate it. There was no doubt that gases were given off during blowing.

See under X., page 526.

PATENTS.

Improvements in the Process of and Apparatus for Evaporating or Drying. F. M. Robertson, London. Eng. Pat. 20,166, December 10, 1890.

THROUGH a horizontal cylindrical chamber, filled partly with the material to be dried, passes a shaft which carries a screw of about the same diameter as the vessel, which on rotating pushes the material towards the forward end. Openings near both ends of the chamber, on a level with its lowest point, are connected to large outside tubes which run parallel with it, and lead the materials back to the starting point, where they come again under the influence of the screw. A current of hot or cold air is maintained through the upper parts of the chamber, taking up the moisture from the materials and from the exposed surfaces of the screw.—H.

Improvements in Filters. R. W. Barker, London. From H. Goodacre, Lexington, U.S.A. Eng. Pat. 1817, March 12, 1891.

THE improved filter consists of an upright cylinder, with double walls packed with a non-conducting substance. It

* Any of these specifications may be obtained by post by remitting 5s. The price now fixed for all specifications, postage included—to Sir Henry Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

is provided with an air-tight cover connected to a pipe from the source of supply. The draw-off cock is at the lower end, and above it is a box carrying a removable ice-drawer. The filtering medium consists of an upper and lower circular disc, each disc having a central hole, and several concentric series of alternating flanges and slots. Between the two discs is a series of porous filtering cylinders graduated to fit one within the other, and arranged so as to form a number of annular filtering compartments, the upper disc being perforated opposite the upper end of each alternate compartment, and the lower disc opposite the lower end of each intermediate compartment, a bolt passing through the two discs keeping them and the cylinders in position. The unfiltered water passes through the slots in the upper disc at the upper end of each alternate compartment, through the filtering cylinders to the slots and compartments of the lower disc, and the filtered water is thoroughly cooled before being drawn off by flowing round the ice-box.—E. S.

Improvements in Digesting Apparatus. W. H. Munns, London. From G. Kallenberger, Cleveland, U.S.A. Eng. Pat. 6057, April 8, 1891.

The object of this invention is to produce a digesting apparatus in which the process may be carried on in a continuous manner. The invention comprises a conduit, which has a receiving and a discharge end. Two valves are arranged near the discharge end and a chamber is formed in the conduit between the valves. A similar arrangement is provided at the receiving end. Suitable horizontal cylinders, with piston and valves, open at one end into each of the above-mentioned chambers. For details of the mode of working, which here specially refers to the digestion of straw for paper-making, the specification must be consulted.—E. S.

Improvements in Distilling and in Apparatus therefor. P. A. Attout, Paris, France. Eng. Pat. 21,698 (under International Convention), May 16, 1891.

A DESCRIPTION of a rather complicated apparatus is here given, by means of which the liquid to be purified is successively filtered, boiled, cooled, again filtered, and finally distilled.—A. L. S.

Improvements in and relating to Evaporating Apparatus. R. Harvey, Glasgow. Eng. Pat. 11,034, June 29, 1891.

THE improvements have reference to evaporating apparatus of the kind known as multiple effects, in which evaporation of the liquid, such as sugar juice, is effected by vertical steam-heated tubes, held between tube plates fitted in the lower parts of upright evaporating vessels. The improvement consists in filling the steam drum only partially with the evaporating tubes, and leaving a large return passage for the liquid at one side of the chamber, the space being partitioned off from the heating tubes, whereby a better circulation of the liquid is secured during evaporation. The tubes are further set out in such a way as to leave clear passages between them radiating from the point where the heating steam enters the drum or "calandria," with a view to the better distribution of the steam to all the tubes. The accompanying figures show one of the arrangements.

Here A_1 represents the tube, drum, or "calandria," with the enlarged passage, b_2 on one side thereof. The heating steam enters at 2, and reaches the "calandria" through the passages a_{11} , and the farther tubes by the channels A_2 (in plan). The resulting vapour passes through b_2 , and by the corresponding passages a and a_1 to the next evaporator.

EVAPORATING APPARATUS.

—B.

Improvements in Appliances for Saturating Air, Oxygen, and other Gases with the Vapours of Ether or other Volatile Fluids. A. T. Danks, Melbourne, Australia. Eng. Pat. 151, January 4, 1892.

A HORIZONTAL brass cylinder is secured in ends provided with feet or flanges forming a stand. One end is fitted with a cover, having a central hole for the admission of the required air or gas. Inside this cylinder are several concentric cylinders, plain and perforated, arranged alternately, the former being secured to the cover and the other end, the latter being held in position by discs. The annular spaces surrounding the perforated cylinders are filled with flannel, which is wrapped round them, the perforations being left uncovered for the free passage of the air or gas. The volatile fluid on being poured in is absorbed by the flannel; the air or gas is then admitted, preferably under pressure, through the hole in the cover, and after passing through, and between the concentric cylinders and the flannel, passes out at the other end thoroughly saturated.

—E. S.

Improvements in connection with the Use of Aluminium and Aluminium Alloys. G. Pickhardt, Bonn, Germany. Eng. Pat. 581, January 12, 1892.

THIS communication relates to the application of aluminium or any suitable alloy of it, either in the form of plates or

sheets, perforated by drilling or punching, or in the form of gauze woven from spun or drawn wire, to the construction of percolating surfaces of screens, sieves, and similar articles.—D. A. L.

Improvements in Apparatus for rapidly Heating Liquids. B. Zeitschel, Berlin, Germany. Eng. Pat. 1210, January 21, 1892.

THIS is an apparatus for quickly and continuously heating a small current of liquid, and consists essentially of a number of super-imposed hollow annular discs of thin metal connected together by numerous small tubes, encased within a jacketed cylinder of the same material and heated from below by means of a gas burner. The cold liquid enters the cylinder jacket at the lowest point, rising to the top where it enters the uppermost of the hollow discs, whence it finds its way gradually to the lowest. Here it reaches a central upright tube, by which it leaves the apparatus in a heated condition. The whole may be placed within an ornamental stand, its principal use being to provide hot water for baths and for other domestic purposes.—B.

Improvements in Apparatus for Distilling Water in the Presence of Air, and for communicating Heat thereto, and for Supplying Water and Air thereto, and Delivering Water therefrom. N. Hunting, Albany, N.Y., America. Eng. Pat. 3013, February 16, 1892.

THE patentee produces distilled water, aerated without special appliances, by evaporating the impure or saline water at low temperature, and condensing the vapour, in the presence of atmospheric air, thereby approximating to the action of the evaporating process in nature. One of the examples given is a domestic apparatus in connection with a hot-water supply of the ordinary description.

A hot water coil heated from the kitchen fire circulates and heats the water in a cistern from which the vapour rises through a large central tube into a casing overhead which carries a cold-water cistern, the bottom and sides of which are exposed to the rising vapours. These condense and collect in an intermediate annular water space where they remain at a moderately high temperature and can be drawn off as required. An overflow leads thence into another cistern outside, in which the water is allowed to cool and to serve as fresh water supply. Air is admitted and retained in the evaporating cistern and the casing, and circulates therein in contact with the vapours.—B.

Improvements in or Relating to Apparatus for Filtering Liquids. W. P. Thompson, Liverpool. From D. Williamson, New York, U.S.A. Eng. Pat. 3064, February 17, 1892.

THIS invention relates to rotary or centrifugal filters, in which the walls of the rotary vessel are composed of the filtering material and allow the liquid to pass through by the action of centrifugal force. The improvement consists in making the rotary vessel slightly conical, the wider part being at the top, in order to allow the precipitate to work its way slowly upward and out over the edge into suitable channels, thus preventing its accumulation on the sides.

The specification describes a filter constructed on this principle.—B.

Improvements relating to the Utilising of Heated Air in Drying Apparatus. H. Leydecker, Glückstadt, Germany. Eng. Pat. 4224, March 3, 1892.

WHEN materials are dried in direct contact with heated air the current is quickly saturated with moisture and is withdrawn from or drawn through the materials at a rapid rate, leaving them at a comparatively high temperature, whereby a certain amount of heat is wasted.

The patentee obviates that loss by passing the moisture-laden air through a range of pipes in a second heating chamber, which pipes give up the acquired heat to another current of air which passes directly through the materials in the second chamber. The second current may then be led through pipes into a third chamber where a third current of air is heated, and the operation repeated until nearly the whole of the heat has been extracted.—B.

Improvements in Indicators for Montejus and Similar Apparatus. J. M. C. Paton, Nottingham, Eng. Pat. 4367, March 5, 1892.

THIS improvement relates to indicators for montejus or other similar apparatus for forcing thick liquids into higher receptacles, filter-presses, or against pressure, in which case ordinary floats for indicating the upper and lower levels of the liquid are inconvenient or impracticable owing to the thickness of the liquid. The inventor inserts two tubes into the upper faces of the vessels, both projecting to a convenient height above the vessel and closed at the top. Small floats are inserted through the tubes, one to the upper and one to the lower level of the liquid, each provided with a rod, and with a cone at the upper end making electrical contact with the closed end of the tube as the liquid reaches the highest or lowest level respectively.—B.

Improvements in Evaporating Apparatus. H. H. Lake, London. From T. Craocy, Bay City, Michigan, U.S.A. Eng. Pat. 5325, March 17, 1892.

THE inventor proposes to evaporate brine and to produce salt in an apparatus indicated in the accompanying figures in vertical and cross section.

EVAPORATING APPARATUS.

F is the outer and D the inner shell of the vertical evaporating vessel. The inner shell forms a fire-box E into which the fuel is admitted through the conical top and passage O, raised thereto by the elevator O₁, and distributed over the fire-grate C by the spreader Q, shaft P, and gearing P₁. The products of combustion pass through the annular boiling pan by the tubes or passages N into the smoke-chamber L, whence they issue by the chimney shafts M M. The vapour is condensed in the hood H by means of the water jet I₁, the combined waters descending

by the well I and pipe J aided, if desired, by a suction pump. The lower end of the evaporating pan is fitted with two water legs S leading to the inclined passage S₁ with elevator S₂ for the removal of the deposited salt. The fuel may be admitted and the salt removed in other convenient ways. U and V are doors for access, and A brick walls supporting the whole.—B.

Natural Coke in Australia. Eng. and Mining J., February 13, 1892, 206.

NATURAL coke, having a very close resemblance to the manufactured article, has been discovered at the Brelli Pass Mines, New South Wales. The seam, which occurs in a coal measure covering 550 acres, is composed partly of a coal of about the same description as ordinary Australian coal and this coke. The junction of the two is clearly defined, and can be traced through the entire workings. In comparison with the manufactured article, the natural coke is a little the heavier, and contains less fixed carbon and a much smaller percentage of ash and sulphur. It is said that it burns without smoke and can be mined at a cost much below that of the cost of manufactured coke.

—W. S.

The Use of Mineral Oil Residues as Fuel for Glass Furnaces. J. Malyschew. Zap. imp. russk. techn. obszcz. 1891, 25, 98; Chem. Zeit. 16 (Chem. Rep.), 85.

IN the first glass furnace using mineral oil residues put up at Bekunow's glass works in Astrachan, two Nobel hearths were used, the flames being led through a vertical tube into the actual furnace, which was of similar design to the French reflector furnaces. A high temperature was attained by this means, but after four or five days' work the tube which led the gases into the furnace and the stage on which the pots stood, fell in. The second furnace was of oblong form, and was large enough to take eight pots, four on each side, the Nobel hearths being in the middle. Last the flame should impinge directly on the pots, whereby they would have been destroyed after a single fusion, the space between the rows was increased to about two feet. The increased size of the furnace prevented its temperature rising as freely as before, and it was useless for refractory glass. It was, however, at work for four years.

In the plan now adopted, the glass is fused direct on the hearth of the furnace, which closely resembles a Siemens regenerator furnace. There are two gas regenerators and one regenerator for air on each side of the furnace. Into one of the gas regenerators, previously brought to a red heat by a previous part of the operation, petroleum residues are allowed to flow, and are volatilised by contact with the hot bricks, the vapours streaming through red-hot flues and entering the furnace in a gaseous state. Coke remains as a decomposition product of the residues and covers the walls of the regenerator. The layer gradually increases until it partially blocks the exit flues, and causes a rise of pressure in the regenerator which is indicated by the gas blowing off at a safety-valve. The stream of oil is then diverted to the next regenerator, air being at the same time let into the first regenerator, the coating of coke of which burns, and the products of the combustion (which are not completely oxidised) are allowed to enter the furnace

through the same tube as that conveying the mineral oil gas. Fresh air meanwhile is heated in a separate regenerator and meets the combustible gases in the glass furnace itself. While the gas and the air flow into the furnace from one side, the regenerators on the other side are in connexion with the chimney. The products of combustion pass through these regenerators and escape at a fairly low temperature; should coke from a previous operation remain in one of these regenerators, it is not burnt out because the spent gases are free from oxygen. The mineral oil is allowed to flow into the regenerator for a period of 20 to 30 minutes, at the end of which time the influx is stopped altogether for about five minutes in order that the residue in the regenerator may be completely gasified, whereupon fresh oil is turned into the second regenerator.

The furnace gives a high temperature, the flame being white and depositing soot only at the beginning of each period. The soot falls in flakes into the furnace upon the molten glass, an occurrence which is rather an advantage than not. An attempt to burn off the coke more quickly, by blowing in air, proved a failure, as the temperature produced was so high as to fuse the arches of the regenerator. According to the investigations of Schibaew and the author, the heating of glass furnaces by any atomising arrangement is impracticable. Eighty poods of mineral oil residues sufficed to melt 250 poods of glass.*—B. B.

PATENTS.

A Process for Recovering Cyanides from Coal-Gas. W. L. Rowland, Philadelphia, Penn., U.S.A. Eng. Pat. 22,347, December 22, 1891.

THE object is to remove the cyanides from coal-gas into the ammoniacal liquor, and to recover them therefrom. To the water in the washers or scrubbers a soluble salt of iron is added. On passage of the gas, first of all insoluble carbonate, sulphide, or hydrate of iron is obtained, but gradually ferrocyanide of ammonia is formed, the cyanides being thus removed. Excess of iron is to be guarded against, otherwise a large quantity of sulphide of iron is formed, which tends to clog the scrubber. The ammoniacal liquor is subsequently distilled in the usual form of still and the ferrocyanide recovered from the settled waste liquor by precipitation with an acid iron salt; or a second portion of salt of iron or oxide of iron may be added to the liquor just before or during distillation, when by the boiling off of the ammonia in the presence of an excess of the iron salt the soluble ferrocyanide of ammonia will be converted into an insoluble double salt, the ferrocyanide of iron and ammonia, which may be separated afterwards by settling or filtration, in which case it is mixed with insoluble lime salts if lime has been employed in the distillation. The settlings are treated with excess of lime, which decomposes the insoluble ferrocyanide, and a soluble lime salt is obtained which is removed by filtration. The liquor is boiled, and potassium or sodium chloride is added so as to precipitate all the ferrocyanide as double ferrocyanide of lime and alkali, or the liquor may be acidified and boiled, when the double ferrocyanide of lime and ammonia will be precipitated. On boiling with a carbonate of the alkali an alkaline ferrocyanide is obtained.—T. L. B.

Gas Generator for the Distillation of Mineral Oils and the Combustion at a Distance of a Part of the Whole of the Products of the Distillation applicable to Apparatus for Lighting and Heating. L. Sepulchre, Herstat, Belgium. Eng. Pat. 2367, February 8, 1892.

IF but a small portion of the exposed wick of a mineral oil lamp could be caused to ignite and burn, its flame and the heat therefrom would cause a distillation of the oil continually ascending in other parts of the wick, not ignited. It is conceivable that such vapours could be led off by a suitable conduit to a distance, and there ignited and burnt.

* One pood = 36·11 pounds.

It is to carry this idea into effect that the proposals of the patentee are made. The focus of distillation is kept as cool as possible by suitable air-currents arranged to act in jets upon the wick, and the intense focus of combustion is transported not only to a distance from the burner and the wick, but further above the metallic deflectors, and for heating flames, even very high above the deflectors. All the metallic parts of the burner and of the reservoir can thus be at a considerable distance beneath the intense focus of the flame and are consequently absolutely safe as regards heating. The petroleum contained in the reservoir does not vaporise, hence the following important results are obtained: (1) complete safety; (2) constant and uniform feeding of the focus of distillation insured; and (3) the wick being removed from the intense focus of combustion is consumed slowly. The distillation of the gases requiring the combustion of but a small quantity of gas, the result is that a very large part of the totality of the gases distilled is reserved (almost in a state of purity) for the intense combustion, thus effecting a considerable saving of oil per unit of light or of heat, compared with all other known apparatus. With this arrangement absolute suppression of all smell and of all smoke even of all redness at the extremities of the flame is secured; this result is due to the mixture of pure hydrocarbon gases and air, which mixture in the journey between the two distinct foci becomes intimate, and is thus under the best possible conditions for a complete combustion.—D. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Preliminary Heater for the Distillation of Petroleum.
F. Fuchs, Chem. Zeit. 16, 314—315.

The author describes the explosion of such heaters in two cases at one of the largest Austrian factories. Such heaters are used in petroleum factories for two purposes: (1) as fuel economisers, and (2) for separating mud-substances contained in petroleum.

The author accounts for the explosion of these heaters as having been occasioned by the pressure of gases produced by the formation of vapours of benzine (petroleum spirit), which had not sufficient room for evaporating, and suggests as a preventive the use of cylindrical heaters instead of the usual square ones, the former being capable of bearing a higher pressure.

The condensing pipes placed in the heater must not be put higher than the centre thereof to prevent them becoming uncovered when the quantity of petroleum in the heater decreases, thus avoiding the formation of benzine vapours.

Those heaters with a dome must also be supplied with two pipes for the removal of the benzine vapours formed, to the condenser, and, finally, they must also be furnished with a manometer and thermometer, which will give the opportunity of controlling both the pressure and temperature of the heater.—P. D.

Percentage of Guaiacol in Wood Creosote, &c. J. Bongartz, Apoth. Ztg. 1891, 6, 697; Chem. Ztg. Rep. 1892, 16, 6.

The official creosote from beech-wood tar consists of a mixture of guaiacol and varying quantities of different creosols and xlenols. The author showed that creosote contains 50—60 per cent. of guaiacol. The latter has a boiling point of 206—207° C. and the specific gravity of 1.133 at 15° C. (not 1.117 as stated in text-books). The guaiacol is soluble at 15° in 85 parts water and eight parts petroleum spirit. Concentrated sulphuric acid gave a slight yellow colour only, whilst the commercial preparations of guaiacol are at once more or less reddened by the concentrated acid.—J. L.

See under 11., page 510.

PATENTS.

Improvements in Apparatus for Extracting Tar and Ammonia from Gas. A. A. Lister, London. Eng. Pat. 7092, April 21, 1891.

THE improved "washer" or apparatus for removing the tar and ammonia from gas consists of a circular drum or casing standing vertically and containing two wooden perforated discs, nearly fitting the interior of the drum and arranged to revolve in opposite directions. The washers are placed in series in line one behind another on a foundation built in ascending steps. Clean water flows into the highest washer and leaves it by an overflow syphon-pipe at about the centre, so that the drum is always about half full of water; thence it flows to the next washer, and so on in succession, emerging from the last or lowest one of the series charged with tar and ammonia removed from the gas. The gas flows through the washers in the opposite direction, entering at the lowest one and leaving at the highest. The wooden discs carry up the water, and by reason of their revolving in contrary directions in each casing, cause the gas to thoroughly mix with the water and so remove the tar and ammonia. Partitions may with advantage be placed in the drums to more completely bring the gas in contact with the wet perforations and surfaces of the discs. Each disc is mounted on a short horizontal shaft entering the side of the casing, the inner ends being supported in bearings carried on a central standard or cross-bar. A pulley is fitted on the outer end of each shaft, and a series of pulleys to correspond is fixed on an over-head shaft, revolution of the discs in opposite directions being obtained by means of open and crossed belts. The wooden discs and their perforations are left quite rough in order more effectually to carry up the water.—D. B.

Improvements in the Manufacture of Ammonia and Tar from Nitrogenous Organic Substances, and in Apparatus relating thereto. W. P. Thompson, Liverpool. From P. Kuntze, Asschersleben, Germany. Eng. Pat. 9052, May 28, 1891.

THIS invention relates to the manufacture of ammonia and tar from nitrogenous organic substances whereby as a source of nitrogen the extensive turf moors and peat bogs are proposed to be utilised. The treatment referred to consists in:—

(a.) Subjecting the broken-up and dried material to charring in a charring furnace, which is heated by producer gases, generated at a later stage of this process, while the resulting mixture of tarry, aqueous, and nitrogenous vapours is submitted to an igniting process for decomposing the organic nitrogenous vapours, in the presence of superheated steam and great surfaces of light red-hot porous refractory matter, into ammonia and hydrocarbons, which are separated and absorbed in the usual manner; and

(b.) Treating the residue from the charring process in a generator situated below the charring furnace by means of hot air and superheated steam in order to liberate the fixed nitrogen and convert it into ammonia, the resulting mixture of ammonia and permanent gases being separated in any well-known manner and the gases applied for heating purposes. The generator for converting the residue into gas is arranged below the charring furnace in order to allow of the residue from the latter dropping directly from the charring furnace into the generator, whereby the process becomes a continuous one.—D. B.

Improvements in Methods of Storing Inflammable Spirits or Highly Volatile Hydrocarbons. B. H. Thwaite, Eng. Pat. 9180, June 1, 1891.

AROUND the storage tank, which may be circular or rectangular, the patentee provides an annular space to serve as a water seal of such depth as will allow the side plates of a cylindrical movable cover to be sealed. Even when the contents of the tank have been withdrawn the cover, which resembles the dome of an ordinary gasometer, is so arranged that there is a continual and close contact of the top plates thereof with the surface of the oil. The upper part of this storage tank cover is made to serve as a water tank, in which a layer of water is maintained. For balancing the weight of the cover an arrangement similar to that used for counterbalancing the moveable part of ordinary gas holders is provided. In order to withdraw from the holder any possible accumulation of gas an escape pipe arrangement is provided, the vertical limb of which works in a vertical and annular hydraulic seal—this allows for the lift of the cover plates. In ordinary gas works the outlet of this seal is connected to the gas mains—the upper part of the space (if any) between cover of oil tank and surface of oil is then connected with the gas distributing mains, by which means any accumulation of gas simply diffuses with the ordinary town lighting gas, and there is always established under the cover a pressure of gas which will itself prevent the admission of air. For tank steamers the patentee uses a sheet iron float cover having flexible connexions to the store tank sides. This cylindrical cover, with its annular or surrounding hydraulic seal, is so formed that it floats on the surface of the oil, and as the latter is withdrawn it falls with the oil, there being sufficient play in the flexible sides to allow this, and thus as the oil is withdrawn there is not left behind any serious accumulation of combustible gas.—D. B.

Gas Generator for the Distillation of Mineral Oils, and the Combustion at a Distance of a Part or the Whole of the Products of the Distillation applicable to Apparatus for Lighting and Heating. L. Sepulchre, Herstat, Belgium. Eng. Pat. 2367, February 8, 1892.

Improvements in the Manufacture of Asphaltum. J. A. Dubbs, Allegheny, Pennsylvania, U.S.A. Eng. Pat. 3026, February 16, 1892.

THIS invention relates to the manufacture of asphaltum from crude petroleum or petroleum residues, and consists in the combination of the crude petroleum or petroleum residues, when subjected to heat, with sulphur.—D. B.

IV.—COLOURING MATTERS AND DYES.

A Nitro-ketone derived from Camphorsulphophenols. P. Cazeneuve. Compt. Rend. 114, 838—840.

AMETHYLCAMPHOPHENOL-SULPHONE, $C_{11}H_{13}(SO_2)(OH)_2O$, and the isomeric amethylecamphophenolsulphonic acid $C_{11}H_{13}(SO_2.OH)(OH)O$ are the most important camphorsulphophenols derived from camphor.

On treating these compounds with dilute nitric acid, their sulphur is eliminated, with formation of sulphuric acid and at the same time a nitro-compound, $C_{11}H_{11}O.NO_2$. This compound crystallises from alcohol in beautiful yellow needles, melting at from 47 to 48 °C. In small quantities these crystals can be sublimed without alteration, larger quantities distil at about 262 °C. with partial decomposition. The nitro-compound is capable of decomposing the alkaline carbonates, and combines easily with the caustic alkalis, forming salts of the general formula $C_{11}H_{10}M'O.NO_2$, some

of which are distinguished by the dichroism of their crystals. The reaction of this compound with phenylhydrazine, with which it forms an azone, proves it to be a nitro-ketone, which, by means of tin and hydrochloric acid, is converted into a base of very remarkable properties. The nitro-ketone dyes silk yellow without intervention of a mordant, and is, according to the author, probably a derivative of a hydropropylbenzene.—C. O. W.

Grawitz' Recent Patent Improvements in Aniline Black. H. Schmidt. Chem. Zeit. 16, 502—503, and 531—532.

See under VI., page 519.

The Origin of Colour. The Constitution of Coloured Nitro Compounds. H. E. Armstrong. Proc. Chem. Soc. 1892, 112, 101.

IN a communication in March 1888 (Proc. Chem. Soc. 1888, 27), in which the relation between colour and constitution was discussed, it was maintained that in the case of azo-dyes, the rosanilines, methylene-blue, &c. colour was conditioned by a quinonoid structure. The author states the opinion at which he has arrived, viz., that in the case of coloured compounds which have been fairly well studied, it is so generally true that a quinonoid formula is applicable, that the reconsideration of the formula of any coloured substance is warrantable if it do not come within the rule. The term "quinonoid" must, however, be understood to include compounds of the type of benzil; and it is to be noted that in the case of closed chain compounds, it appears to be essential that at least one of the quinonoid carbon atoms be associated with a dyad radicle, and that the ring itself be unsaturated; the presence of two ortho- or para-carbonyl groups in a saturated ring apparently does not condition colour.

Nitro-compounds have from an early period attracted the author's attention, as he states that they do not come within the suggested "colour rule." It is well known, however, that nitro-compounds are not all coloured, many which are commonly described as yellow being obtained white when prepared from pure materials and precaution is taken to remove the phenolic compounds which are so frequently formed even from hydrocarbons during nitration; from this it follows that the nitro-group does not *per se* condition colour. A comparison of ortho- with para-nitrophenol affords striking confirmation of the correctness of this conclusion; the former alone is coloured, being intensely yellow, very volatile, and insoluble in water; whereas para-nitrophenol does not volatilise with steam, and is fairly soluble in water. To what is the difference ascribable? It can scarcely be otherwise than to a difference in structure beyond that involved in a mere difference in the relative positions of the radicles. On comparing the methoxynitrobenzenes prepared from ortho- and para-nitrophenol, Dr. Kipping and the author find not only that they are both colourless, but that they agree as closely in their general properties as do most isomeric compounds containing the same radicles; it is particularly noteworthy that they are about equally volatile with steam. The non-correspondence of the two nitrophenols is rendered far more striking by the correspondence of the compounds prepared from them by methylation, and the conclusion is strengthened thereby that they are not mere position isomerides: it therefore appears justifiable to represent ortho-nitrophenol by a quinonoid formula, which may readily be done by transferring the hydroxylic hydrogen to the NO_2 group, thus transforming it into a dyad group, NO_2H , a change which admittedly attends the formation of so-called nitrosophenol (quinonehydroxime) (cf. Nietzki, Organische Farbstoffe, Berlin, 1889). On this hypothesis, the name *quinoneorthonitroxime* may be suggested for "ortho-nitrophenol."

Para-nitrophenol, although itself colourless, yields coloured metallic derivatives, in the formation of which a change of structure must be involved, according to the view here advocated.

As only para- and ortho-compounds can have quinonoid formulae, it would follow that metanitro-derivatives must be colourless; but actually metanitraniline has an intense yellow colour. There are but two ways out of this difficulty: to assume that metanitraniline either is not (as ordinarily obtained) a uniform substance, or that its structure is not really that of an aminonitrobenzene. There is, however, no other obvious mode of representing it; and although Dr. Kipping and the author have spent much time in trying to deprive it of its colour, they have been unsuccessful; they have found, however, that it yields a practically colourless benzoate, a result regarded as strong presumptive proof in favour of the view that metanitraniline is not what it is supposed to be, and it is therefore proposed to submit it and similar compounds the closest study.

PATENTS.

Improvements in the Manufacture of Colouring Matters derived from Anthraquinone. B. Willeox, London. From the "Farbenfabriken vormals F. Bayer und Co.," Elberfeld, Germany. Eng. Pat. 4871, March 18, 1891.

This specification, comprising 18 claims, is an extension of several earlier patents, and also describes certain new dyestuffs belonging to the alizarin class.

I. Oxychrysazin (oxyanthrafin), as shown by the following formulae, occupies an intermediate position between alizarin and alizarin-bordeaux.

If oxychrysazin be treated according to Eng. Pat. 8725 of 1890 (this Journal, 1891, 537) it is converted into a colouring matter resembling alizarin-bordeaux, the reaction in this case also taking place in two stages. By substituting erythroxyanthraquinone for oxychrysazin in the above process a dyestuff is obtained resembling in its properties that prepared from anthraquinone according to Eng. Pat. 18,729 of 1890 (this Journal, 1891, 917).

II. In Eng. Pat. 18,729 of 1890 and Eng. Pat. 1883 of 1891 (this Journal, 1892, 29) the preparation of colouring matters is described from anthraquinone or dichloro- or dibromo-anthracene by the action of sulphuric anhydride. The same process can be applied to substances such as tribromo- and tetrabromo-anthracene, dibromo-anthracene-tetrabromide, bromo-anthraquinone, and anthranol. The colouring matters are similar to those already described, and dye wool mordanted with alumina salts a violet, and with chromium salts a blue colour.

III. By treating alizarin-bordeaux in a sulphuric acid solution with oxidising agents according to Eng. Pat. 12,715 of 1890 (this Journal, 1891, 759) it is converted into a new colouring matter which is now termed "Alizarin-cyanine R." According to Eng. Pat. 17,712 of 1890 (this Journal, 1891, 917), an intermediate product formed in this process gives a new colouring matter when treated with ammonia. It has now been discovered that two cyanines are produced according to the conditions under which the oxidations are performed. If the temperature be kept low and an insufficient quantity of manganese dioxide added, a product is obtained called "alizarin-pentacyanine." By employing a higher temperature and more manganese dioxide, using

arsenic acid or acting on alizarin-pentacyanine with sulphuric acid alone, alizarin-hexacyanine is produced. The two substances are pentahydroxy-anthraquinone and hexahydroxy-anthraquinone. The former is more easily soluble in nitrobenzene and glacial acetic acid, whereas the latter dissolves in sulphuric acid to a redder colour than the pentacyanine and possesses a stronger fluorescence. The solutions exhibit characteristic absorption bands.

IV. In the preparation of the above-mentioned alizarin-penta- and hexa-cyanines by means of manganese dioxide, intermediate compounds are formed which have been termed anthra-diquinones, since they contain a true quinone group in addition to the double ketone group of anthraquinone. By reduction with sulphurous acid they are converted into hydroquinones which are the cyanines, and hence these quinones may be produced by oxidation of the cyanines. By dissolving Alizarin-cyanine R in potash solution and passing air through the liquid the potassium salt of the quinone separates out. The salt is then decomposed with an acid at a low temperature.

V. The formation of these quinones and their reduction to the cyanines points to an improvement in the method for the production of the latter on that described in Eng. Pat. 12,715 of 1890. The melt obtained by treating alizarin-bordeaux with manganese dioxide in a sulphuric acid solution is poured into water and treated with sodium sulphite until it smells of sulphurous acid. The mixture is then boiled up, filtered, and the dyestuff re-dissolved.

VI. By oxidising the cyanines in an ammoniacal solution by means of air, or by the action of ammonia on those quinones described under IV. corresponding to the cyanines described under III., similar colouring matters to Alizarin-cyanine G are obtained, the preparation of which is described in Eng. Pat. 17,712 of 1890.

VII. The processes described under IV. and V. can also be applied to the quinoline derivative of alizarin-bordeaux or dihydroxy-alizarin blue of Eng. Pat. 8725 of 1890, or to the hexahydroxy-anthraquinone produced according to Eng. Pat. 17,712 of 1890, or Eng. Pat. 18,729 of 1890. The diquinones obtained from these bodies can also be treated with ammonia forming quinone-imides and giving somewhat greener shades than the original products.

—T. A. L.

The Production of New Bases and of Azo-Colouring Matters therefrom. Brooke, Simpson, and Spiller, Limited, and A. G. Green, Hackney Wick, Middlesex. Eng. Pat. 6376, April 14, 1891.

New azoxy- and azo-derivatives of *o*-toluidine are obtained by the alkaline reduction of nitro-*o*-toluidine—

which melts at 92° C. The nitro-*o*-toluidine is formed by reducing fluid binitro-toluene (Bernthsen, Ber. 15, 3016, this Journal, 1883, 169), and is also obtained together with the nitro-*o*-toluidine melting at 107° C. by the nitration of *o*-toluidine in sulphuric acid at a low temperature. In the latter case the nitro-*o*-toluidine melting at 92° C. is precipitated from the mother-liquor from which that melting at 107° C. has separated, by the addition of an alkali. The new azoxy-*o*-toluidine—

melting at 149° C., and the new azo-*o*-toluidine—

melting at 175° C. are produced in a similar manner to that described in Eng. Pat. 14,304 of 1889 (this Journal, 1891, 131) for the production of isomeric bodies from the nitro-*o*-toluidine melting at 107°. They are similarly employed for the production of dyestuffs by diazotisation and combination with naphthol and naphthylamine sulphonic acids, and with phenols and amines generally and their sulphonic acids. A colouring matter dyeing unmordanted cotton a brilliant scarlet unaffected by acids is obtained by combining diazotised azoxy-*o*-toluidine with 1:4 naphthol sulphonic acid in an alkaline solution. If azo-*o*-toluidine be employed the shade is somewhat bluer.—T. A. L.

The Manufacture and Production of New Diazo-Dyes, and of Intermediate Products in their Preparation. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 7713, May 4, 1891. Second Edition.

THE 1:1'-amido-naphthol sulphonic acid described in Eng. Pat. 9676 of 1890 (this Journal, 1891, 538) is capable of combining with diazo-compounds to form disazo derivatives, which dye wool a deep blue black from an acid bath. Various amines may be employed such as aniline, *o*- and *p*-toluidine, *m*- and *p*-xylylene, *p*-anisidine, α -naphthylamine, and acetyl-*p*-phenylene diamine. Also the isomeric 1:1' amido-naphthol sulphonic acid, obtained by fusing with a caustic alkali the naphthylamine disulphonic acid prepared by sulphonating naphthylamine sulphonic acid 8 of Ger. Pat. 40,571, can be substituted for the above mentioned 1:1' amido-naphthol sulphonic acid in the formation of these disazo compounds. The combination is performed in the well-known manner, but preferably by allowing one molecular proportion of the diazo-compound to combine in a faintly acid solution of one molecular proportion of the amido-naphthol sulphonic acid, and afterwards making the solution alkaline and running in the second molecular proportion of the diazo-compound which may be derived from the same amine as the first or from a different one or from a sulphonic acid such as sulphanilic acid.—T. A. L.

Production of Blue Colouring Matters. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, and Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 7961, May 8, 1891.

THE acid colouring matters known as "Patent Blues," described in Eng. Pat. 12,796 of 1888 (this Journal, 1889, 701; 1890, 286), and Eng. Pat. 11,822 of 1888 (this Journal, 1889, 980), which are sulphonic acids of *m*-oxy- and *m*-amido-tetra-alkyl-diamidotriphenyl carbinols yield blue colouring matters of great value when oxidised. The oxidation may be performed by means of fuming sulphuric acid, but preferably it is conducted in an aqueous solution by means of iron salts or chromic acid. 24.6 kilos. of tetra-ethyl patent blue (the monocalcium salt of the disulphonic acid of *m*-oxy-tetra-ethyl-diamido-triphenyl carbinol) are dissolved in 200–300 litres of water, boiled, and a solution of 8 kilos. of CrO_3 in water slowly added. After about two hours, when the oxidation is complete and the solution is free from chromic acid, the liquid is filtered and evaporated to dryness. The colouring matters dye wool and silk in uniform blue shades from an acid bath fast to soap, light, and air.—T. A. L.

Production of Blue Dyestuffs. S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 8407, May 15, 1891.

A PROCESS for obtaining blue dyestuffs for mordanted cotton of the thionine class from *o*-toluidine. 16.5 kilos. of the nitro-amine of mono-ethyl-*o*-toluidine, are dissolved in 150 kilos. of concentrated hydrochloric acid at about 5° C. After standing some time, the clear solution, which contains the hydrochloride of *p*-nitroso-ethyl-toluidine—

is diluted with water, cooled with ice and reduced with 15 kilos. of zinc dust. When the solution is colourless, the free acid is neutralised and 24.8 kilos. of sodium thiosulphate and 10 kilos. of potassium bichromate are added. A solution of mono-ethyl-*o*-toluidine hydrochloride is then poured in, and after the addition of 120 kilos. of zinc chloride, the whole is oxidised by means of 30 kilos. of potassium bichromate, raised to the boil and kept boiling for an hour. The dyestuff which separates out is mixed with chromium oxide, from which it is separated after filtration by extraction with hot water and precipitation with salt, when it forms small green crystals.—T. A. L.

The Manufacture and Production of Colouring Matters derived from Anthraquinone and Alizarin Blue. B. Willcox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 8702, May 21, 1891.

THE anthraquinones (alizarin cyanine quinones) described in Eng. Pat. 4871 of 1891 (see above) for new mordant dyestuffs by condensation with phenol, dihydroxy-benzenes and their homologues, α - and β -naphthol and their carboxylic acids or other substitution products. The condensation is most easily effected by means of sulphuric acid, and hence the formation of these new dyestuffs starting with alizarin bordeaux may be performed in one operation without separating the quinone. New colouring matters are also obtained by condensing with resorcinol, salicylic acid, *p*-hydroxy-benzoic acid, and *o*-eresotinic acid, the quinone of hexa-hydroxyanthraquinone isomeric with alizarin hexacyanine described in Eng. Pat. 18,729 of 1890, and Eng. Pat. 17,712 of 1890 (this Journal, 1891, 917). The alizarin bordeaux described in Eng. Pat. 8725 of 1890 (this Journal, 1891, 537), its analogues and the polyhydroxy anthraquinones obtained therefrom by further oxidation, and other compounds of this class such as Alizarin blue-green, Alizarin-green, and Alizarin indigo blue described in Eng. Pat. 14,353 of 1888 (this Journal, 1889, 770) and Eng. Pat. 15,121 of 1888 (this Journal, 1889, 772), form new dyestuffs by treatment with ammonia. The reaction taking place appears to be the substitution of an amido for a hydroxy group. It is generally complete at ordinary temperatures, but heating with an excess of ammonia on the water-bath is sufficient in all cases. The dyestuffs thus obtained differ from the originals by the redder or yellower colours of their solutions in sulphuric acid, and this test serves to indicate the end of the reaction. With chromium mordants on wool, these colouring matters dye a greenish blue.—T. A. L.

Production of Blue Colouring Matter. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, and Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 9943, June 11, 1891.

By the action of fuming sulphuric acid on anthrachrysone (a derivative of anthraquinone) a new colouring matter is obtained which gives blue shades on chrome-mordanted wool and cotton, fast to light and fulling. Anthrachrysone is stirred into fuming sulphuric acid at a temperature not exceeding 50° C. until the solution becomes bluish-green. It is then poured on to ice, boiled, dissolved in an alkali, and precipitated by an acid from this solution. The colouring matter forms a black powder dissolving in concentrated sulphuric acid with a violet red, in ammonia with a bluish violet, and in dilute caustic soda with a reddish-brown colour.—T. A. L.

The Manufacture and Production of New Basic Dyestuffs. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 10,619, June 22, 1891. Second Edition.

AN extension of Eng. Pat. 4476 of 1888 (this Journal, 1889, 280), which describes the preparation of dyestuffs of the Nile blue series obtained by the condensation of the nitro-*o*-dimethyl- and diethyl-*m*-amido phenols with α -naphthylamine and its derivatives, such as ethyl- α -naphthylamine and di-methyl- α -naphthylamine. The present specification describes the employment of benzyl- α -naphthylamine in place of α -naphthylamine and its derivatives mentioned in the preceding patent. Benzyl- α -naphthylamine has been obtained by the action of benzylamine on α -naphthylamine, but is more easily prepared by condensing two molecules of α -naphthylamine with one molecule of benzylchloride in toluene at the temperature of the water-bath. The hydrochloride of the base is obtained by passing hydrochloric acid gas through its ethereal solution. The following proportions are given for preparing a greenish-blue dyestuff. About 69 kilos. of nitroso-diethyl-*m*-amido-

phenol hydrochloride and 54 kilos. of benzyl- α -naphthylamine hydrochloride in 100 litres of spirit are heated on the water-bath under a condenser. The reaction sets in at about 60° C., and sufficient heat is evolved to raise the solution to the boil. It is kept boiling for 3 to 4 hours and then allowed to cool, when a crystalline precipitate separates which can be used directly for dyeing and printing. Other salts than the hydrochlorides may be employed in the above condensation, or one of the components may be in the form of base, but in this latter case it is preferable to use acetic acid as a solvent. The colouring matter obtained from nitroso-dimethyl-*m*-amido-phenol gives a redder shade of blue, and its hydrochloride is sparingly soluble in water, so that it is best employed as its more soluble sulphate.

—T. A. L.

Improvements in the Manufacture of Colouring Matters.

H. H. Lake, London. From K. Oehler, Offenbach-on-the-Maine, Germany. Eng. Pat. 10,861, June 25, 1891.

By combining diazotised benzidine or tolidine with one molecule of amido-hydroxy- α -naphthalene disulphonic acid, and then with *m*-hydroxy-diphenylamine or tolylphenylamine, blackish-blue colouring matters for cotton are obtained. Eleven kilos. of tolidine (or the equivalent quantity of benzidine) in 75 kilos. of muriatic acid of 12.5 per cent. strength and 500 litres of water are cooled to 0° C., diazotised with 7 kilos. of sodium nitrite, and poured into a solution of 18 kilos. of amido-hydroxy- α -naphthalene disulphonic acid in 700 kilos. of 1.5 per cent. caustic soda. The intermediate compound thus formed is converted into the new dyestuff by adding a solution of 9.25 kilos. of *m*-hydroxydiphenylamine, or of 10 kilos. of *m*-hydroxy-tolylphenylamine, in 250 litres of water and 2 kilos. of caustic soda. The colouring matter is precipitated by salt, pressed, and dried. The sodium salts of the new dyestuffs are blackish, bronze-coloured powders, soluble in water, giving red to bluish-violet solutions, from which concentrated hydrochloric acid precipitates a bluish-violet acid, which dissolves in concentrated sulphuric acid with a blue colour.—T. A. L.

The Manufacture and Production of New Dyes of the Rosaniline Series and of New Materials therefor.

J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 11,275, July 2, 1891.

By condensing resorcinol with *p*- or *o*-toluidine, or with *m*-xylylene the following compounds are respectively obtained:—*m*-hydroxy-phenyl-*p*-tolylamine, *m*-hydroxy-phenyl-*o*-tolylamine, and *m*-hydroxy-phenyl-*m*-xylylamine. It has been discovered that the alkylated derivatives of these compounds when condensed with tetra-alkyl-diamidobenzophenones yield basic colouring matters of the rosaniline series, and these on sulphonation give soluble acid dyestuffs. The following details of the various operations are given:—

1. About 100 kilos. of *m*-hydroxyphenyl-*p*-tolylamine, 20 kilos. of caustic soda, 400 kilos. of methyl alcohol, and 40 kilos. of methyl chloride, are heated in an autoclave for 24 hours to 115°–120° C. The methyl alcohol is then distilled off, and the residue washed first with caustic soda, then with water, and finally dried at 100°. The *m*-methoxyphenyl-*p*-tolylamine thus obtained is sufficiently pure for the preparation of dyestuffs. It forms a thick oil, distilling with decomposition at about 360° C., and is preferably distilled in vacuo. After standing some time it solidifies, and can then be crystallised from benzene, when it melts at about 68° C.

2. The condensation with tetramethyldiamidobenzophenone is performed in a similar manner to that described in Eng. Pats. 4850 and 5038 of 1884 (this Journal, 1885, 204, 279). About 22 kilos. of *m*-methoxyphenyl-*p*-tolylamine, 27 kilos. of tetramethyldiamidobenzophenone, and 35 kilos. of phosphorus oxychloride are diluted with 8 kilos. of toluene, and heated on the water-bath in a vessel provided with a stirrer for about half an hour. The melt is then poured into brine, boiled and extracted with toluene or heavy oil. The colouring matter which remains behind

is dried at 60° C., and powdered. It is slightly soluble in water, more readily in alcohol, and gives violet-blue shades on wool and on cotton mordanted with tannin.

3. This product is sulphonated by mixing it with an equal weight of anhydrous sodium sulphate, and adding the mixture to 2½ times its weight of fuming sulphuric acid containing 24 per cent. of SO₃, the temperature not being allowed to rise above 10° C. When a sample is completely soluble in alkali, the melt is poured into ice water, and the solution nearly neutralised with caustic soda. The dyestuff is then precipitated with sodium sulphate, filtered, and dried. It dyes wool violet-blue from an acid bath.

—T. A. L.

New or Improved Colouring Matter or Dye and Methods of Extracting and Utilising the Same. E. Schweich and E. Bucher, Wittington Park, Chester. Eng. Pat. 11,298, July 3, 1891.

A BROWN mordant colouring matter, to which the name "Prosopine" is given, is obtained from the "heartwood of the species '*prosopis*' commonly called cashaw tree," by some process of extraction, and the extract can be used, together with a mordant, either by itself or with some other dyewood, for dyeing, printing, or staining, &c.—T. A. L.

Process of Dyeing Silk Solid Black, by Means of Alizarine, Flacopurpurine, Anthrapurpurine, and Mixtures of these Bodies. O. Imray, London. From the "Farbwerke vormals Meister, Lucius und Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 11,327, July 3, 1891.

THE methods for dyeing silk black and dark brown with logwood do not give colours fast to acids, soap, or alkalis. The process described in the present specification gives fast blacks, produced as follows:—Boiled silk is mordanted with ferric sulphate of 30° B., well soaped and treated with the quantity of potassium ferrocyanide and hydrochloric acid corresponding to the oxide of iron on the fibre. The silk in this way receives a grounding of Prussian blue. It is then passed into a bath at the boil containing cutch and tin salt corresponding to the degree of weightening required, and after washing, having been worked in a second bath of cutch, it is ready for dyeing. It can also be prepared by mordanting the crude or boiled silk with tin salt solution of 30°, washing and treating with ferric sulphate and potassium ferrocyanide as described above, and finally passing it through a boiling bath of cutch, when after washing it can be dyed. For this purpose the silk, treated according to either of the foregoing methods, is worked for about half an hour at 65° C., in a weak soap bath containing 2–2½ galls. of water to every pound of silk, a quantity of soap, varying from 15–20 per cent. of the weight of the silk, according to the hardness of the water, and a quantity of alizarin from 20–50 per cent. of the weight of the soap, sufficient to produce the desired shade. The temperature is then raised to the boil, and the silk worked at 95° C. for three-quarters of an hour. Finally, a further quantity of soap is added, the bath is heated to boiling, and the silk worked for half an hour, in order to give it lustre and touch. After dyeing, the silk is washed for a few minutes in a bath at 30° C., and made slightly alkaline with sodium carbonate. It is then well washed, treated with an acid, some size, and an oil emulsion, and is finally shaken out and dried. The colour thus obtained is said to be fast to acids, alkalis, and sunlight.—T. A. L.

Manufacture of Yellow Azo-colouring Matters Striking on Mordants and Absolutely Fast against the Action of Felling, Soap, and Light. O. Imray, London. From the "Farbwerke vormals Meister, Lucius und Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 11,328, July 3, 1891.

THE colouring matters described are obtained by combining diazotised diamido-sulphobenzide (diamido-

diphenylsulphone), its derivatives and homologues with hydroxy carboxylic acids. The colouring matters dye chrome-mordanted wool fast to fulling, soap and light. In the case of the colouring matters from diazotised diamido-diphenylsulphone and salicylic acid and from diazotised diamido-diethoxy-diphenyl-sulphone this fastness is absolutely perfect. 12.4 kilos. of diamido-diphenyl-sulphone and 12 kilos. of hydrochloric acid are dissolved to a 10 per cent. solution in water and diazotised by the addition of 12 kilos. of hydrochloric acid and a solution of 6.9 kilos. of sodium nitrite in 35 litres of water. The tetrazo compound which separates out from moderately dilute solutions is added at 0° C. to a 10 per cent. solution of 16 kilos. of *o*-cresotinic acid and 33 kilos. of calcined sodium carbonate. The combination is complete in 12 hours when hydrochloric acid is added, the colouring matter filtered off and used preferably as a paste. In addition to the derivatives and homologues of diamido-diphenyl-sulphone, the diamido-dinaphthyl-sulphones may also be employed.—T. A. L.

Improvements in the Manufacture of Basic Naphthalene Colouring Matters, and of Sulpho Acids thereof. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik" Ludwigshafen, Germany. Eng. Pat. 11,629, July 8, 1891.

By heating together rosindone with *o*-toluidine or *m*-xylydine and the hydrochlorides of the two latter, colouring matters are obtained which give red shades different from those given by phenyl-rosinduline. These homologues of phenyl-rosinduline as well as that one obtained by employing *p*-toluidine give mono-sulphonic acids when treated with ordinary sulphuric acid at the temperature of the water-bath (cf. Eng. Pat. 15,259 of 1888; this Journal, 1889, 877). On further sulphonation with fuming sulphuric acid, disulphonic acids are obtained which are homologues of azo-carmines and are yellowish-red to bluish-red dyestuffs readily soluble in hot, but sparingly soluble in cold water, especially in presence of mineral acids. The bases *o*-tolyl-rosinduline and *m*-xylyl-rosinduline yield higher sulphonic acids on further sulphonation which are readily soluble in cold water. The *p*-tolyl-rosinduline decomposes on further sulphonation.—T. A. L.

Improvements in the Manufacture of Colouring Matters for Dyeing and Printing derived from Benzidine and its Analogues. B. Willeox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 11,663, July 9, 1891.

By reacting with one molecule of tetrazo-diphenyl chloride or one of its homologues or derivatives on one molecule of an aromatic hydroxy carboxylic acid, such as salicylic acid, *o*- or *m*-cresol carboxylic acid or resorcylic acid, an intermediate product is obtained which, on boiling in an alkaline, neutral or acid solution evolves nitrogen and is converted into a derivative of *p*-amido-hydroxy-diphenyl. The following equation illustrates the course of the reaction—

The dyestuffs obtained by this process are valuable not only on account of their dyeing mordanted wool, but also because they can be employed in calico-printing, in this respect resembling alizarin. The colours produced are yellow varying from a red to a brown shade.—T. A. L.

The Production of Fast Yellow Mordant Dyeing Azo Dyestuffs. A. Bang, Leeds. From G. A. Uahl, Barmen, Germany. Eng. Pat. 960, January 18, 1892.

SUBSTITUTES for fustic are obtained by diazotising the α -, β -, γ -, or δ -, β -naphthylamine sulphonic acids or the α -naphthylamine sulphonic acids of Laurent or Piria, and combining them with salicylic acid and *o*- and *m*-cresotinic acids. On chromium mordants these colouring matters like fustic are absolutely fast to milling and have moreover the advantage of being faster to light. They also dye unmordanted wool fast to milling and light. The shades obtained from the β -naphthylamine sulphonic acids are greenish yellow, those from the α -naphthylamine sulphonic acids being more orange-yellow. Similarly salicylic acid gives a greener shade than the cresotinic acids. (cf. Eng. Pat. 17,583 of 1887; this Journal, 1888, 839).—T. A. L.

Improvements in the Manufacture of Colouring Matters H. H. Lake, London. From A. Leonhardt and Co., Mühlheim-on-the-Maine, Germany. Eng. Pat. 1231, January 21, 1892.

By oxidising the rhodamines obtained, for instance, from dialkylated *m*-amidophenol or *m*-amidocresol and phthalic acid, by means of potassium permanganate, dyestuffs of a more yellowish-red shade are produced. The colouring matters themselves or their leuco-compounds may be employed. Eight kilos. of rhodamine from succinic acid are dissolved in 400 litres of water and 20 litres of acetic acid, and oxidised in the cold by the addition of 4 kilos. of potassium permanganate in 100 litres of water. The whole is then boiled up, filtered, and the colouring matter precipitated by the addition of zinc chloride and salt. By employing less permanganate the product is more bluish-red. The dyestuffs obtained according to this invention are basic, forming salts with acids. They dissolve in water or spirit, giving scarlet solutions with a brilliant green fluorescence, and are adapted for dyeing or printing mordanted or unmordanted cotton or silk, the latter when dyed showing a yellowish fluorescence.—T. A. L.

Improvements in the Production of Black Dyes suitable for Dyeing Wool. S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 2718, February 11, 1892.

AN extension of Eng. Pat. 9214 of 1885 (this Journal, 1889, 700), and of Eng. Pat. 7067 of 1889 (this Journal, 1890, 385). A diazotised amine or sulphonic acid thereof is combined with α -naphthylamine monosulphonic acid (1.6 or 1.7). The amidazo-sulphonic acid thus obtained is diazotised again and combined with phenols or amines or their derivatives. 24.5 kilos. of sodium naphthionate are diazotised and combined with 24.5 kilos. of 1.6 or 1.7 α -naphthylamine sodium sulphonate in presence of sodium acetate. The amidazo-disulphonic acid thus formed is diazotised by means of muriatic acid and 7 kilos. of sodium nitrite, and separates as the diazo compound. If combined with 35 kilos. of β -naphtholdisulphonic acid R in an alkaline solution a black dyestuff is obtained which resembles naphthol black.—T. A. L.

The Manufacture of New Colouring Matters or Dyes. P. Monner, St. Fons, Lyons, France. Eng. Pat. 4677, March 9, 1892.

COLOURING matters to which the name "Anisolines" is given are produced by heating salts of the rhodamines with the haloids of methyl, ethyl, amyl, or benzyl, forming alkylated rhodamines.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Vulcanisation of Waterproof Fabrics. Industries, 12, 1892, 498.

Of late years there has been a great development of the waterproof trade in the direction of increased variety in the fabrics employed. In fact, 15 years ago the number of cloths used for the purpose were very few, but at present we see an almost endless variety of wool, silk, and cotton goods, alone and in combination with each other. Scotch and Yorkshire woollen tweeds now constitute the largest portion of the dealer's stock-in-trade, the black or blue paramatta—a mixture of wool and cotton—being conspicuous. The nature of the cloth has to be considered before it is submitted to any vulcanising process. To briefly summarise the "spreading" part of the process, it may be said that the rubber is mixed with sulphur or other curing agents and is rolled out into thin sheets and dissolved to a paste in coal naphtha. This paste is then spread on the cloth by the knife edge of what is known as the "spreading machine." The spread cloth passes then over a steam chest, whereby the naphtha is volatilised and the rubber left as a thin coat. Several of these coatings are required to make up the necessary thickness of proof, and then the material is ready to be vulcanised. This is done by one of three processes, viz., (1) steam cure, (2), cold cure (Parke's process), (3) dry heat.

In the first process the proofed cloth is rolled round a sheet-iron drum, and exposed in a "vulcan pan" to high-pressure steam at about 275° F. for an hour or more. This process is not much used for fabrics, as it is found impossible to ensure equal heating owing to the non-conducting nature of the material, whereby the outside layer is overheated before the inner is heated sufficiently. In the second, or cold cure process, the vulcanising agent is chloride of sulphur. This is dissolved in bisulphide of carbon in the proportion of 1 to 40 parts by volume. In applying this process the rubber surface is made to pass over a roller which is kept revolving in the solution. In spite of the disagreeable nature of the chemicals, this process has been and is very largely used, though the "cure" is not a complete one, being merely effected on the surface where the solution has come in contact with the rubber. This process is not considered a very satisfactory one, and the use of the mercuric liquid bisulphide of carbon, with its attendant fire risks, is likely to become obsolete, a satisfactory substitute having been found for it. The liquid being merely a vehicle for the chloride of sulphur to ensure the absorption of the latter by the rubber, it is clear that as long as it has a solvent action on the rubber its chemical constitution is of no great moment.

The cold cure, so long without a rival, has been supplanted to a great extent by the third, or "dry heat process," which, although used to a certain extent for some time, was not worked on a large scale until, in 1877, Mr. Waddington invented his improved dry-heat stove. This stove consists of a long wooden chamber lined with zinc and fitted in its interior with a system of rollers so arranged that the cloth occupies, in its passage, the necessary time to effect vulcanisation at the one operation, and, being continually on the move, no portion can receive more or less heat than another. In this way the rubber coating is vulcanised all through, and not merely on the surface, as in the cold cure. It may be asked whether the dry heat injures the textile fabrics? There is no fear of this if the process is carefully carried out, and the heat not allowed to rise higher than is absolutely necessary. When cured by this process the goods can be depended on to remain soft and pliable during cold weather, and, what is even of more importance, they will not decompose by being kept in stock in a hot climate. It is to this dry heat method of vulcanising that Mr. Fawcitt referred (this Journal, 1889, 368), and he claims that, by the employment of metallic iodides—notably those of antimony, lead, and tin in conjunction with sulphur—the proof can be cured in a shorter time and at a lower heat than when sulphur alone is used. The writers agree with the author that the cost of the iodide is likely to militate against its adoption.

How is this vulcanising action to be explained? The reply is made that there really is very little known regarding the true nature of the change, whether it is a true chemical reaction or merely a physical fact. It is generally stated that in the ordinary vulcanising process, when a mixture of rubber and sulphur is submitted to high-pressure steam for an hour or so, 3 per cent. of sulphur is chemically combined, the rest being physically held and capable of abstraction by solvents. Some expert experience, however, leans to the opinion that not more than $\frac{1}{2}$ per cent. of sulphur is chemically held if insolubility in caustic solutions is to be taken as a proof of chemical combination. The reaction with chloride of sulphur is generally allowed to be due to the substitution of hydrogen in the rubber by chlorine. That a substitution compound exists is shown by passing a current of chlorine gas into a solution of rubber in chloroform, when a white solid body is formed, and hydrochloric acid is evolved. A similar reaction occurs in the case of bromine, though we have it on the authority of Gladstone and Hibbert that no reaction whatever occurs in the case of iodine. Chloride of sulphur is found to be the most practicable way of applying chlorine to rubber, though many other compounds of chlorine act in a similar manner.

PATENTS.

Improvements in the Treatment of Vegetable Fibrous Matters to obtain Fibres therefrom. P. W. Nicolle, Portland Place, Jersey, and J. Smith, Camberwell. Eng. Pat. 18,284, November 13, 1890.

For obtaining the fibrous portions of vegetable substances, e.g., *Behmeria nivea*, flax, hemp, New Zealand flax, &c., these materials are steeped in a solution of creosote or phenol, or of any tar acids. A solution of any of these acids in combination with an alkali, of a strength of about one-half per cent. by weight, may also be employed. For flax and hemp a cold solution is used for 24 or 48 hours. Refractory vegetable substances, such as ramie bark, should first be placed in a cold solution for 24 hours, then passed through rollers, and finally treated with a boiling solution for three to six hours. The pulpy substance of New Zealand flax is removed by means of corrugated rollers or knives, &c. At the end of the process the fibres are passed through rollers and washed.—H. S.

Improvements in Machines for Decorticating Ramie and other Textile Plants. G. E. N. I. E. Subra, Paris, France. Eng. Pat. 19,100, November 25, 1890.

The object of this invention is the complete removal of the ligneous matter and of the leaves of ramie, as well as of the epidermis which covers the fibrous parts of the plant. The machine used for this purpose consists of two pairs of cylinders, one pair being smooth or slightly fluted and both turning in the same direction. This pair is for the preliminary crushing of the ligneous matter of the stalks. The second pair, the stripping cylinders, by which the wood, the leaves, and the epidermis are entirely broken and disengaged, are formed of metal blades or plates firmly fixed upon the parallel shafts, and forming grooves. Their speed is greater than that of the crushing cylinders, and the latter therefore detain the stalks long enough to give the stripping cylinders sufficient time to effect their work. The plates of these cylinders are so arranged that they pass between each other when rotating. The edges of the blades are either rounded, square, or sharp, the last form being specially intended for green ramie. The disengaged wood, leaves, and epidermis fall to the ground without the possibility of choking the stripping cylinders. When the operation has taken place upon half the length of the stalks, the operator removes them and presents the opposite or unworked half to the cylinders. The two pairs of cylinders may be arranged horizontally, vertically, or obliquely, and are mounted upon wooden or metal frames of suitable shapes and dimensions. The machine may be driven by hand or other power.—H. S.

Process for Cleansing or Purifying Woollen Fabrics. C. D. Abel, London. From Philips and Mathée, Rheinland, Germany. Eng. Pat. 19,252, November 26, 1890.

THE patentees have found that sulphurous acid, sodium bisulphite, and all compounds which give off sulphurous acid on the addition of an acid, have the property of removing from woollen fabrics the impurities which are accumulated during the spinning, weaving, and fulling processes. These impurities become to a certain extent insoluble under the influence of the usual carbonising process, and are detrimental to the dyeing of the fabrics, producing stripes, spots, and other defects. To effect their removal the fabrics are, after the carbonising process, soaked in pure water together with mineral acids, and then treated for some time with aqueous sulphurous acid or with sodium bisulphite, &c. The liquid is then drawn off and the remainder of the sulphurous acid and of the impurities are removed by means of soda-lye or of any other alkaline liquid. Finally the fabrics are thoroughly rinsed with water. Without the previous treatment with sulphurous acid the solution of the impurities by means of soda only is stated to be very imperfect.—H. S.

An Improved Fireproof Fabric. L. Allard, Paris, France. Eng. Pat. 19,579, December 1, 1890.

THIS fabric is composed of a mixture of animal fibres and asbestos, felted together in varying proportions by any suitable means. It is designed to replace ordinary felt where the latter is unable to withstand extraordinary heat.

—H. S.

Improvements in the Cleansing, Treating, or Washing of Wool and like Animal Fibres, and in Apparatus employed therefor. A. Ambler, S. Ambler, and F. Ambler, Willesden. Eng. Pat. 20,267, December 12, 1890.

THIS refers to a modification of Eng. Pat. 13,626 of 1889 (this Journal, 1890, 856). The liquor and wool passes along a series of superposed channels, first in one and then in another (usually the opposite) direction, and then returning, and so on, the object being to cause the liquor and wool to come into close contact without felting. Near the end of the channel, and below a perforated portion of it, is fixed a sand box to receive precipitated solid matters.

—H. S.

Improvements in or relating to the Preparation and Dressing of Silk and other Fibre. G. F. Priestley, Halifax. Eng. Pat. 123, January 3, 1891.

SILK-TUFTS have hitherto been made by means of the so-called "filling engine" which produces them looped at one end and fringed at the other, which is an objectionable form of tuft. Instead of this machine the patentee uses an ordinary form of gillbox provided with fallers and heckle pins, made to travel by screws through the fibrous material. The "film of fibre," as it issues from the machine, is wound round a fluted roller, and afterwards severed by means of a knife, and the strips, thus cut, are then formed into tufts. The circumference of the fluted roller must be such as to produce the required length of tuft.—H. S.

An Improved Machine for Decortiating Ramié. P. Faure, Limoges, France. Eng. Pat. 1445, March 7, 1891.

THE stalks to be decorticated are placed on a table, where they are seized by a pair of feeding rollers, conveyed to a trough, and subjected to the action of a beater drum, whereby the woody parts are broken and partially separated from the fibrous elements of the plants.—H. S.

Improvements in the Waterproofing of Textile Materials. J. G. Smith, Liverpool. Eng. Pat. 6698, April 18, 1891.

IN this invention the solutions employed in the process of waterproofing textile fabrics are described, and the inventor avails himself of the property of paraffin wax, stearin, or any fatty acid to dissolve as much as 100 per cent. of its own weight of gutta-percha or india-rubber, when heated to from 100° to 110° C. Generally such a solution of 15 parts of india-rubber in 100 parts of paraffin wax is prepared, and the solution so obtained is either directly or after suitable dilution with benzine or benzol (benzene) applied to the material to be waterproofed.—C. O. W.

Improvements in the Treatment of Samples of Crude Wool for Estimating Purposes. A. Frayssé, Antwerp, Belgium. Eng. Pat. 11,717, July 9, 1891.

THIS invention has to do with the detection of the so-called rendement of crude wool which is usually done by mere inspection and touch, but this frequently gives rise to errors. The patentee, therefore, subjects a sample of crude wool to the action of two machines, which remove therefrom first all foreign substances, e.g., thistles, grain, sand, &c.; and secondly, the grease of the wool; then the pure wool is dried and weighed, and the absolute yield of wool hereby ascertained. The thistles, &c., are removed by a rinsing and carding machine, in which a jet of cold water under pressure first removes all the grains, sand, and other granular impurities; then the fibres are freed from thistles, &c., by passing the wool between a carding cylinder and a series of carding rollers. The washing machine in which the wool is afterwards subjected to the action of a number of boiling baths or lye washes for the removal of the grease, consists of two rectangular tanks, and of a feeding apparatus between them. The machine is further provided with two rollers, so that the wool can be alternately conveyed from one tank to the other. The tanks can be heated from below, and have perforated false bottoms, below which each tank has a tap for discharging the lyes when exhausted. After the grease is removed, the wool is dried in the open air and weighed, and finally some small samples of it (about 200 grms. each) are weighed, then absolutely desiccated, and weighed again. For the last two operations one of the tanks is used as a sort of wool-conditioning apparatus. It is stated that from the results thus obtained the proportion of wool in the whole sample, and thence in the whole bale, can be calculated.—H. S.

Improvements in or connected with the Manufacture of Textile Articles with Fringed Edges. A. Bancroft, Manchester. Eng. Pat. 15,056, September 5, 1891.

THIS invention is for making upon textile fabrics fringed edges the threads of which will not fray or become loose, by saturating certain parts of the fabrics with gum, size, &c., and then cutting them into fringes the threads of which are cemented together. This is effected by stamping upon the material in the piece a quantity of gum or size, &c., in suitable forms, allowing it to dry, and then cutting these parts of the fabric into fringes which are stiff and not liable to curl. The gummed parts, while still soft, may be coated with gold, silver, or other metallic leaf, or the parts forming the fringe printed upon or dyed.—H. S.

An Improved Compound Fabric. F. J. Bugg, Ipswich. Eng. Pat. 18,003, October 20, 1891.

SHEETS of "composition compressed or lay leather" are covered with felt, woollen cloth, flannel, canvas, calico, or other suitable textile fabric by sizing one surface of each sheet, placing the sized surfaces together, pressing, and drying. Both sides of the leather may be so covered or several sheets stuck together to give the required substance.

—A. G. B.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

So-called "Decolourised" Tannin Extracts. V. H. Soxhlet. Chem. Zeit. 1892, 16, 15—16.

DECOLOURISED tannins are required for three distinct purposes:—(1.) As a stiffening and weighting material for silk; such must be absolutely colourless and is prepared from oak-galls. (2.) As a mordant for cotton, for which sumac is particularly applicable, chestnut-wood, divi-divi, bablah, and others being also used. (3.) For the actual process of tanning, the object being to remove either an excess of colouring matter or an objectionable colour, as in the case of quebracho and hemlock. The mixture of one extract with another will sometimes serve to correct the colour; a French sample of "*Extrait de quebracho decoloré*" was found by the author to be a mixture of quebracho and chestnut-wood.

Gondolo's method of decolourising by means of bullocks' blood gives good results, particularly with Virginian sumac and chestnut-wood, although the latter does not, as a rule, require decolourising for the tanner.

Lead acetate can be very successfully applied under certain conditions; the addition of 0.4 kilo. per 1,000 litres of tannin-liquor, the boiling of the liquor and its subsequent filtration and evaporation are the features of the process. The method gives good results with chestnut, oak, and larch, but is not adapted for sumac, valonia, and other bloom tannins, such as divi-divi and myrabolans, because it leaves such extracts opalescent—a fatal fault in the eyes of dyers. Lead nitrate has been patented for the same purpose in Germany.

Foelsing's patent has appeared in this Journal, 1892, 237; in a recent method by the same author the use of electricity is dispensed with, and he employs antimony oxalate as a precipitant; but Soxhlet points out that a considerable amount of tannin is thus lost.

The author finds that most salts will effect the decolourisation required, to a greater or less extent. Iron, copper, and chromium salts are of course beyond the pale, but sodium sulphate, zinc acetate, magnesium sulphate, ammonium sulphate, and bismuth nitrate can be employed. The last mentioned works well, but is high-priced. To apply these salts, a weak extract (3°—4° B.) is prepared either by the diffusion method or by extraction under pressure at 112°, and to every 1,000 litres of this 250—500 grms. of the salt are added; the liquor is run into basins and allowed to remain with frequent stirring, at 60°—70°, for 1—3 hours. Neutralisation is then effected by addition of borax or sodium phosphate, and the warm liquor passed through a filter-press. The neutralisation is of great importance, because if left acid the liquor will become turbid during the subsequent and concluding process of evaporation to 30° B.

In a very recent patent (this Journal, 1892, 81) strontium compounds are proposed. (Compare also Villon, this Journal, 1890, 820; Jean, this Journal, 1892, 46.)—A. G. B.

Grawitz' Recent Patented Improvements in Aniline Black. H. Schmidt. Chem. Zeit. 1892, 16, 502—503 and 531—532.

GRAWITZ has patented a process (French Pat. 212,082, 1891) which claims to be an improvement on that of Lightfoot (1863), in which aniline hydrochloride, alkali chlorate and copper or vanadium are used. He employs an excess of alkali, or acetates of the alkaline earths, tartrates, oxalates, citrates, &c., to combine with the hydrochloric acid which is set free in the reaction. The following is an example of the bath:—Aniline hydrochloride (1,295 grms.), crystallised sodium acetate (1,020 grms.), tartaric acid (100 grms.), sodium chlorate (207 grms.), and ammonium vanadate (5 grms.), dissolved in water (1,300 cc.). He has since confirmed Nietzki's view that the tetramine (aniline black) resulting

from the condensation of the four aniline residues is a mon-acid base, and therefore three molecules of hydrochloric acid are set free in the reaction. The author points out that hydrochloric acid is also produced by the decomposition of the chlorates; in this respect chromates are superior as oxidising agents. The hydrochloric acid from the "chlorate black" impregnates the fibre, and when the latter is dried slowly the cellulose is converted into hydro-cellulose. In printing, in which one surface only is concerned, the hydrochloric acid does not exert so harmful an effect, and the thickening medium protects the fibre: ferric hydroxide, lead dihydroxide, and lead chromate have been used advantageously, especially the last salt, in aniline black printing. For dyeing, however, these are inadmissible, and it has long been the custom to partially basify the aniline hydrochloride employed by ammonia, and ten years ago exact directions were given for the application of aniline partially converted into hydrochloride. C. Koechlin several years ago proposed the use of aniline tartrate and later of aniline acetate in conjunction with ammonium chloride, substantially in this respect, as now again patented by Grawitz, and it is well known that in the Prud'homme steam aniline black process. An amount of sodium acetate proportional to that of the aniline black formed must be used. Grawitz employs vanadium in the form of ammonium vanadate, and the author finds that the bath prepared according to his directions (see above) becomes turbid within an hour after its preparation, and can no longer be used; in a word, Grawitz' improvement is impracticable. The author shows that the amount of chlorate employed by Grawitz is only sufficient to convert 55 per cent. of the aniline salt into black; taking this into account, therefore, the sodium acetate must be present in large excess, the more so if it be calculated on Kayser's formula for aniline black $C_{12}H_{10}N_2$ instead of Nietzki's $C_{15}H_{15}N_2$.

With regard to the weakening of the fibre, it is remarked that the oxidising agent as well as the free acid is concerned in this, and that in addition to hydrocellulose, Witz' "oxycellulose" is produced. When the oxidation is carried in the dry way to the stage of emeraldine and then completed in the wet way by potassium chromate, a black is obtained which does not rub off the fibre.—A. R. L.

Contribution to our Knowledge of Sumac. W. Eitner. Der Gerber, 1892, 18, 51.
See under XIV.—page 539.

The Dyeing of Smooth Mohair Fabrics and Plushes. E. Weiler. Färb. Zeit. 1892, 155.

MOHAIR piece goods offer considerable difficulties in dyeing as compared with other woollen fabrics or unions. These difficulties are caused through the great stiffness and water-repellent nature of mohair yarns, which prevent the rollers of the "jiggers" from properly gripping the cloth, which consequently keeps slipping upon the rollers. This is the reason why in the dyeing of mohair fabrics the old hand-worked dye-vats are still used. The above-mentioned

JIGGER FOR DYEING MOHAIR FABRICS AND PLUSHES.

drawbacks of the automatic dye vat can be overcome by taking into account in their construction the peculiarities of the material to be dyed.

The side $a a'$ of the jigger is arranged at an angle of 45° ; the perforated diaphragm $b b'$ partitions off that part of the vat in which the steam pipe $c c'$ is arranged. The latter enters the jigger from the right or left and goes to the bottom, where it is bent at a right angle and is then conducted right along the bottom. The horizontal part of the pipe is perforated in such a manner as to allow the steam to go upward only. In $d d'$, instead of the usual circular roller, an elliptical roller is arranged, with as large a longitudinal diameter as possible and well gripping edges. The second roller, e , is a circular grooved roller.

For the dyeing of yarns in this jigger a rake f is arranged along the guiding roller e , which keeps the skeins always in position. In the dyeing of piece goods a gauge is employed instead of the rake.—C. O. W.

The Use of Mineral Pigment Colours in Cotton Dyeing. V. H. Soxhlet. Farb. Zeit. 1892, 151.

THE employment of mineral pigments for the dyeing of cotton has, since the introduction of the coal-tar colours, decreased in a very considerable measure, chiefly owing to the greater ease with which the latter allow of the production of brilliant and cheap shades. There is no doubt, however, that in many cases mineral pigments, even at present, may with advantage be used upon the fibre.

The application of "iron buff" from iron salts is still practised to a considerable extent, on account of its great cheapness and fastness against air and washing. Toluylene orange and cresotine yellow are probably the only coal-tar colours capable of producing similar shades, and are in this way particularly employed for "padding" calicoes. The "buff" obtained by these dyes is superior to "iron buff," as far as fastness against acids is concerned. The production of "iron buff" is exceedingly simple. It is sufficient to treat the cotton to be dyed with the solution of a ferrous or ferric salt, following with a passage through an alkaline bath. The iron salt generally employed for this purpose is "nitrate of iron," i.e., ferric sulphate 40°B. (77°Tw.); very seldom ferrous sulphate is used. The cotton is treated in baths of ferric sulphate at from 2° to 5°B. , hydro-extracted, and then introduced into a sodium carbonate bath at 2°B. Instead of the sodium carbonate bath a lime passage may be adopted. These operations can be repeated in order to obtain darker shades.

On passing yarns or cloth dyed with this "iron buff" through a cold bath containing a solution of ferrocyanide acidulated with sulphuric acid, very fine blue tints are obtained the depth of which is in direct proportion to that of the "iron buff." This blue is scarcely ever produced at present, the artificial dyes yielding brighter and very much faster shades. The only property which might commend this blue to the dyer for occasional application is its great fastness against acids. In dyeing this blue it is advantageous to add to the "nitrate of iron" bath in which the buff is dyed 2 per cent. of "tin crystals." The buff is fixed in the ordinary way in an alkaline bath, and subsequently the blue is developed in a bath of yellow prussiate containing about 2 per cent. of sulphuric acid.

Of other blue colours which might be produced upon the fibre, only molybdenum blue is worth mentioning, which, however, has not, and probably never will, find industrial application.

Nature favours us in every respect with an abundance of yellow colours. They are very numerous amongst the natural dyestuffs, as well as amongst mineral pigments and artificial dyestuffs. But owing to the existence of such a variety of yellow and orange dyes, mineral pigments of these shades are only employed but to a very limited extent. The chromates of lead are almost the only yellow and orange pigments used, and are obtained by the interaction of bichromates and soluble lead salts. The practical method of the application of these colours to the cotton

fibre has been originated by Lassaigue in 1820. Since then chrome-yellow, and especially chrome-orange, has been very extensively used on cotton, the colours being fast to light and washing, and exceedingly simply produced. The modern benzidine and diamine dyes are, however, superseding the chrome pigments, although the latter are much faster to light. The process of dyeing cotton yarns with these chrome pigments consists in well handling the previously boiled yarn in a 2°B. solution of acetate of lead, the hanks are then wrung, and without washing worked in a cold bath containing per 100 of water $4\frac{1}{2}$ kilos. of sodium bichromate and $1\frac{1}{2}$ kilo. of sulphuric acid. The shade being developed, the yarns are well washed and dried. Golden yellows, i.e., redder shades of yellow, are obtained by using for the first bath basic acetate of lead instead of the normal acetate. A beautiful orange is obtained by first treating the cotton in a 5°B. solution of basic acetate of lead (subacetate), then developing the yellow in a second bath with 20 per cent. of sodium bichromate, and finally working in a hot bath containing 12 per cent. (of the weight of the cotton) of lime. The tendency of the yarns dyed with chrome pigments to "rub" or "dust off" may be reduced to a minimum by oiling them.

Cadmium yellow is scarcely ever used on cotton, although nitrate of cadmium is used in calico printing to prevent the sulphuretted hydrogen, given off by the albumen used in the process, from damaging the printed chrome yellow. In order to produce cadmium yellow alone upon cotton, the latter is heated for half an hour in a bath containing $4\frac{1}{2}$ per cent. of cadmium chloride at 60°C. The hydro-extracted cotton is then transferred to a bath containing 4 per cent. of sodium sulphide, whereby the yellow is developed.

Of other mineral salts suitable for dyeing cotton yellow, antimony-orange and sulphide of arsenic may be mentioned. These two compounds, however, are no longer in practical use for dyeing purposes. On impregnating cotton yarns or fabrics with concentrated solutions of tartar emetic or oxalate of antimony, and exposing them subsequently to a current of sulphuretted hydrogen, good orange shades are obtained, although the shades obtained with arsenic are very fugitive if treated with alkaline liquids. This fact and the poisonous nature of the sulphide of arsenic entirely prohibit its use in dyeing. For similar reasons the green chromium arsenite and copper arsenite are never used.

Of considerable importance, especially in calico-printing, are the salts of manganese for the production of a variety of brown shades, technically termed "Bistres." The production of these colours consists in the fixation of manganic hydroxide upon the fibre. For these purposes the fabrics are impregnated with manganese salts and then taken through a chloride of lime solution, when a full brown shade at once appears. Well as this process answers for calicoes, it gives very poor results on hanks. Nor does a passage first through permanganate and then through an acidulated solution of ferrous sulphate answer the purpose any better. Of importance are, however, those processes in which sulphate of manganese together with permanganate is used. The yarns are worked in a solution of sulphate of manganese at 2°B. , hydro-extracted, and subsequently immersed in a bath of permanganate at 1°B. A very good brown shade is obtained, which may be made darker by repeating the operations. These colours darken considerably in the process of drying, though in a very irregular manner, thus causing unevenness. This tendency to unevenness can be counteracted by passing the yarns before drying through a bath of acetate of iron at $\frac{1}{2}^\circ \text{B.}$

Extremely fast shades of grey may be obtained by passing yarn through a solution containing 4 per cent. of mercuric nitrate, hydro-extracting and then treating in a solution of sodium sulphide. Owing to the great fastness of the grey shades obtained in this manner no poisonous effect need be apprehended, although special precautions may be required to protect the workmen who are treating the yarns in the solution of the mercuric salt.—C. O. W.

PATENTS.

Improvements in Transparent Coloured Materials for Decorative Purposes. A. McLean, West Kensington, Middlesex. Eng. Pat. 8296, May 14, 1891.

GELATIN dyed with aniline colours is made into thin sheets which are dipped in a bath of thin oil varnish and hung up to dry. The sheets thus prepared may be cut up into pieces of various shapes and patterns and applied by means of some adhesive material to the surfaces to be decorated. Patterns in more colours may be produced by cutting out from the coloured gelatin certain portions, which will constitute the pattern. By running over this gelatin uncoloured or suitably coloured gelatin, a number of colour effects may be obtained.—C. O. W.

Improvements in the Process of Dyeing, Tanning, and Mordanting Leather, Teazled Fabrics, or other Porous Materials, and in Apparatus employed therefor. J. Goldschmidt, Fürth, Bavaria, Germany. Eng. Pat. 19,397, November 10, 1891.

THE distribution of dyes on surfaces of leather and other fabrics has heretofore been effected by the application of centrifugal force or by means of brushes or rolls. These methods are tardy and liable to damage the grain of the leather or surface of the fabric. By this invention the dye and mordant are distributed by means of compressed air. The hides are placed on discs superimposed on one another, with sufficient working distance between each, in an air-tight vat; as each disc is put in its place the dye is distributed over the hide by means of a rubber pipe leading from the reservoir of dyestuff, from which the dye is forced by compressed air. When all the discs are in position the vessel is closed and the compressed air turned on; the dye is thus forced into the fabric. The mordant may be applied in the same manner. For drawings of apparatus for which claims are made the original specification must be consulted.

VII.—ACIDS, ALKALIS, AND SALTS.

Sulphuric Acid Manufacture in 1891. R. Hasenclever. Chem. Ind. 1892, 15, 69.

It is now recognised that the reactions that take place in a vitriol chamber can be aided by bringing about a more intimate contact of the gases by causing them to traverse narrow tubes in their passage from one lead chamber to another, the advantage being more marked at the end of the operation, and several small chambers at the exit end being therefore provided through which the gases are driven and in which they are intimately commingled. At Petrowitz in Austria, and at Ghent in Belgium, lead chambers in the

form of gasometers are in use, but nothing has yet been published to prove that they possess any particular advantages. The coke, both in the Gay-Lussac and Glover towers, can be replaced by brick or stone exposing sufficient surface for the work of absorption, the reason for the change being that the coke generally used becomes gradually clogged and inefficient, and further that it reduces nitrosulphuric acid, yielding carbonic acid and nitric oxide, the latter being useless at that part of the process at which it finds its way back to the chambers.

A considerable proportion of the impurities in sulphuric acid can be avoided by freeing the gases from dust after leaving the pyrites burners and before entering the chambers. A further quantity can be got rid of by deposition before the chamber acid goes to be concentrated. By pursuing this system at Griesheim, the residue left by evaporation can be reduced to one-third or one-fourth of its usual amount, e.g., from 0.009 to 0.003 grm. per litre.

On account of the high price of platinum, considerable alterations have been made in the methods of concentrating sulphuric acid to 66° B. Faure and Kessler have proposed an improvement consisting in the use of a flat platinum vessel provided with a leaden head. A construction specially recommended is that in which a series of tubes are arranged spirally and soldered to a cylinder the lower edge of which enters the liquid seal of a platinum dish. The system adopted by Négrier consists of porcelain dishes, arranged one above the other in terrace form, resting upon iron plates and heated from beneath,—the sulphuric acid dripping from one to the other. Scheurer-Kestner has devised an apparatus of which the lower part is of cast iron while the head is of platinum. The acid first flows into a still wholly of platinum, and then into the cast-iron still with the platinum head. In such an apparatus 4,500 kilos. of sulphuric acid of 95 per cent. strength can be prepared in 24 hours. The weight of the platinum is 18.8 kilos., and that of the cast iron 250 kilos. The amount of platinum dissolved is about 0.15 grm. per ton of acid of sp. gr. 66° B. The cast iron is more attacked when less concentrated acid is produced, the product moreover becoming turbid, but it withstands the action of 95—96 per cent. acid better. Heraeus has made the observation (this Journal, 1891, 460) that platinum alloyed with 10 per cent. of iridium is about twice as resistant as pure platinum. For very concentrated sulphuric acid the same technologist has constructed an apparatus of platinum plated with gold, with which the loss of metal is only about one-seventh that of pure platinum. The plates are prepared by casting gold round platinum 1 cm. thick previously heated to the melting point of the former metal, an alloy being formed at the point of contact, and plates perfectly coated with a thin layer of gold being obtained on rolling. Taking the price of gold at 2,800 marks, and that of platinum at 1,800 marks per kilo., the cost of the metal dissolved by the action of the acid is only 22 per cent. in the case of the gold-plated retort of what it is when unprotected platinum is used. L. Kessler has endeavoured to concentrate sulphuric acid by leading heated air through it in an apparatus made of lead and stone now in use with satisfactory results at Clermont-Ferrand.

The quantity of sulphuric acid produced in Germany in 1890 is estimated at 627,392 German tons.* In the Rhine provinces, Westphalia, Upper Silesia, and Belgium, the output has exceeded the demand, a result contributed to by the fact that in Germany 80 per cent. of the total amount of soda is now made by the ammonia process. An outlet might be found for it in the preparation of artificial manures. It is calculated that the agricultural products of Germany require yearly 640,276 tons of phosphoric acid, of which 156,026 tons are supplied in the form of superphosphate, basic slag, and guano. The balance of 484,256 tons could be supplied by human and animal excrement, which accounts for 553,572 tons, provided no loss occur. Assuming 50 per cent. to be lost (a very moderate estimate) a quantity of 207,170 tons of phosphoric acid is still lacking. This deficiency in phosphoric acid explains the inferiority of Germany in the amount of the crops compared with other lands. The following table shows the yield per hectare in tons of England and Germany respectively:—

	England.	Germany.
Wheat.....	1790	1733
Barley.....	1793	1731
Oats.....	1751	1715
Potatoes.....	1713	821
Pee.....	1772	081

The quantity of phosphoric acid needed in Germany would be 960,000 tons instead of 640,270 tons if the weight of the crops per hectare were as great there as in this country. In the author's opinion, the increased use of artificial manures is a necessity.—B. B.

Concentrating Sulphuric Acid in Gold-lined Platinum Stills. G. Lunze. Eng. and Mining J. 53, 1892, 374.

THE stills in question were brought out by W. C. Heraeus, of Hanau, in Germany, in January 1891 (this Journal, 1891, 460—461). Since that time 15 of them have been supplied to various customers. It was found in all cases which have hitherto come under examination that gold is far less attacked by boiling strong sulphuric acid than platinum, the proportion being 1 to 7 or 10. But a mistake was committed at first in constructing the stills, which has now been detected. At first it was thought that it was sufficient to apply the gold lining merely to the bottom of the stills, or, at most, as high up the sides as the liquid acid reaches. But a year's experience has proved that this is not sufficient; the gold, and therefore the bottom, is certainly perfectly unchanged, but the upper portion of the still, where the platinum is not protected by gold, is corroded as much as before, especially at the point of junction between the platinum and the gold. This has led to ordering new stills to be lined entirely with gold, but keeping the lining much thinner at the upper portion than at the bottom.

At the Gröschel Chemical Works a still was set to work in April 1891, composed of an old platinum dome joined to a platinum-gold bottom.

The still was run night and day, mostly for acid of the highest concentration (96 per cent.). In December 1891 it was examined, and the upper (platinum) portion was found to be corroded, but the gold-lined bottom did not show a trace of either mechanical or chemical action. Therefore a new still, entirely lined with gold, was ordered forthwith.

At the Mansfield Copper Smelting Works a Faure and Kessler still was started in June 1891, furnished with a platinum bottom of 0.4 mm. thickness, lined with 0.1 mm. gold. On January 15 the still was dismantled, having furnished 646 tons of strong vitriol, because the side portions, not lined with gold, were corroded. The bottom, however, plainly showed the hammer marks and exhibited no signs of corrosion whatever.

At the Corbetta Chemical Works a Prentice still was put up on March 9, 1891, lined at the bottom and 3 in. up the sides with 0.05 mm. gold. In January 1892, after having furnished 1,700 tons of strong vitriol, partly up to 96 per cent., it was examined, and the loss in weight was found = 32 grms., all of which was from the upper unprotected portion.

At the Augry works a similar still was started in February 1891, and stopped for examination in February 1892, after having furnished 1,163 tons of strong vitriol, half of it at 96.7 per cent. The loss of weight was 120 grms., or a fifth of what would be expected from an ordinary still under favourable circumstances. Here also the loss manifestly extended only to the unprotected platinum portion.

There cannot be any reasonable doubt that the loss of a stock entirely protected by a gold lining would be less than one-tenth of that of an ordinary platinum still. But two questions may be asked now. First, why must the Heraeus combination be employed instead of an ordinary gilding of the platinum? Secondly, if gold is the only metal in

contact with platinum, why not employ a copper still lined with gold? The first question may be answered as follows: Any ordinary gilding, whether galvanic or igneous, does not at all effect the purpose of protecting the platinum, as the minute film of gold is always more or less porous: the imperfections are speedily found by the boiling acid, and the gold film is soon detached from the underlying metal. But in the Heraeus system a sound and thick lining is produced by pouring melted gold on to the surface of a platinum ingot brought to a white heat, beyond the fusing point of gold. Thus an intimate junction is produced, and a substantial, solid coat of gold is left on the inside, which is never at any point detached from the platinum, and behaves toward sulphuric acid as if the metal consisted entirely of gold. Nor is it possible to employ a base metal in lieu of platinum, for the slightest accidental injury to the thin gold lining would allow the boiling acid access to the base metal which would be instantly dissolved and would cause the still to collapse.

It is true that a gold-lined still costs a good deal more than an ordinary one. Taking a Delpace still, weighing 37½ lb., an inner gold lining of 0.1 mm. for the bottom, and 0.025 mm. for the dome will weigh about 5½ lb., and will raise the cost by about 1,000 dollars, deduction being made for the value of an equal thickness of platinum. This means a small amount for additional interest on plant. But allowing for a yearly production of 2,000 tons of acid, the annual saving of platinum, otherwise dissolved and carried away by the acid, would be at least 2½ lb., worth nearly 300 dollars, and the saving would be in reality very much greater than that, seeing that the total renewal of a still, in which case only two-thirds or three-quarters of the price of new platinum is realised, will occur at very much rarer intervals than at present. It may be assumed that the additional expense of a Heraeus still will be paid for in from one to two years.—W. S.

Notes upon the Estimation of Chlorine in Electrolysed Solutions. L. M. Norton. Technol. Quarterly, 1891, 361.

Improvements in and connected with the Manufacture of Alkali Aluminates. E. Fleischer, Wiesbaden, Germany. Eng. Pat. 7437, April 29, 1891.

THE improvements are in the process for manufacturing alkali aluminates, alumina, caustic alkalis, and carbonates of soda and potash, the alkali aluminate being obtained from aluminous substances by means of alkali sulphates, &c.

The chief difficulty in obtaining sodium aluminate by fusing bauxite and sulphate of soda with the addition of coal has hitherto been the formation of liquors containing quantities of compounds of sodium, sulphur, and iron; furthermore, the fused mass seriously attacks the melting pot. The author avoids the production of the deleterious compound by using in the fusion quicklime or carbonate of lime, so that, as it is stated, the sulphide of iron partially combined with calcium sulphide may be produced in insoluble form. The following rule is given:—"Add to the aluminous substance (clay or bauxite) for every molecule of alumina one molecule of alkali sulphate, and ensure by the addition of iron or its oxides that fully one molecule of iron (including that already contained in the clay) be present for the formation of FeS for every molecule of alkali sulphate or alumina. The lime or chalk is to be reckoned as two molecules for every three molecules of silica, and a further quarter molecule of lime or chalk is to be added for every molecule of alumina." To this must be added, of course, the necessary amount of charcoal.

Fusion is performed at a moderate red heat, not too high, after which the mass is cooled, preferably in closed iron vessels. Lixiviation is performed in the usual way.

To obtain alumina and alkali carbonates, the colourless solution of aluminate is saturated at nearly boiling point with carbonic acid.

Should it be desired to obtain caustic alkali liquor direct from the aluminate solution, the alumina may be precipitated by lime.—T. L. B.

Improvements in the Manufacture or Production of Chlorine and Alkaline Carbonates. C. Kellner, Vienna, Austria. Eng. Pat. 20,713, November 27, 1891.

For the simultaneous production of chlorine and an alkaline carbonate, a heated saturated solution of an alkaline chloride is caused rapidly to circulate in two separate streams through an electrolytical decomposing apparatus, one of these streams, viz., that which flows past the anodes of the apparatus, and to which a small quantity of sulphuric

acid or of a sulphate of the base used has been added, being conveyed, after leaving the apparatus mentioned, through a vessel provided with the alkaline chloride in a solid state, whereby the liquid is again completely saturated before being conveyed back to the anodes; the other stream, viz., that which flows past the cathodes of the apparatus, being subjected, after leaving the said apparatus, simultaneously to a cooling action, to contact with solid alkaline chloride, and to the action of carbonic acid, whereby a carbonate of the alkali present is formed and precipitated from the solution, which is afterwards conveyed back to the cathode cells of the apparatus.

To facilitate the escape of hydrogen set free, carbonic acid is introduced into the cathode cells. The electrolyte is also maintained at such a velocity and temperature as will prevent carbonate of soda from settling within the decomposing apparatus.

IMPROVEMENTS IN THE PRODUCTION OF CHLORINE AND ALKALINE CARBONATES.

To carry out this process an electrolytical decomposing apparatus, consisting of a succession of frames R (Fig. 1) in which the electrodes are arranged, is proposed; these frames, being separated from each other by diaphragms, and having in their upper parts passages $g g'$ (Fig. 2) connected by other passages $h h'$ with the passages $o \dots$ and a , through which the electrolytes are caused to circulate, the passages $g g'$ allowing the gases set free during the electrolytical decomposition to escape separately from the ions. Diaphragms D of a permeable fabric or porous clay are used, the pores of which are filled with gelatinous material mixed with a solution of salt corresponding to that to be decomposed. This is to prevent injurious mechanical diffusion from one cell to another of the liquids treated, and to facilitate circulation of the ions.

The electrodes are made by mixing together powdered retort carbon, thickened solution of wood cellulose in zinc chloride, kneading to a paste, moulding, washing, and then heating in a muffle, impregnating with a hydrocarbon, and then heating several times.

Electrodes are also claimed, the pores of which have been filled up with peroxide of lead obtained either by covering these electrodes with a layer of litharge and sulphate of ammonia mixed together, or by boiling them in a saturated solution of lead acetate, and afterwards electrolytically transforming the lead or oxide of lead thus obtained into peroxide of lead.—J. C. C.

A Process for Recovering Cyanides from Coal-Gas. W. T. Rowland, Philadelphia, Penn., U.S.A. Eng. Pat. 22,347, December 22, 1891.

See under II. page 510.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

The Application of certain Rare Metals for Ceramic Colours. Sprechsaal, 1892, 25, 85.

THE following results are described:—Tungstic oxide (1 part) and a vitrifiable pigment flux (4 parts) yield an extremely stable bright yellow colour. The endeavour was made to replace chromic oxide by vanadic oxide. Pure ferric oxide (64 parts), marble (32 parts), ammonium vanadate (4 parts), and vanadic oxide (2 parts) finely powdered, give a beautiful light rose-coloured sub-glaze for stoneware.—A. R. L.

The Use of Mineral Oil Residues as Fuel for Glass Furnaces. J. Malyschew. Chem. Zeit. 16, (Chem. Rep.) 85.

An Improved Composition or Compound designed to serve as a Substitute for Wood, and also applicable for the Manufacture of Bricks and Crucibles, Retorts, and other Articles of Earthenware. W. A. Kerr, Rhyl. Eng. Pat. 7040, April 23, 1891.

"A VARIETY of tale containing hydrated silicate of magnesia and alumina," or kaolin either free from or containing sand, or other clay or clayey loam is mixed with "sphagnum, which is a kind of moss, or with peat, either in the condition of fibre or granules, or with the said sphagnum and peat combined." The tale or clay is weathered before use, and after having been ground is mixed with the peat by making a pile of the two materials in alternate layers, allowing the mass to "ripen" for 48 hours, and slicing down the pile vertically and passing the mixture into a mixing-press consisting of a hollow cylinder provided with an axial shaft bearing blades inclined so that the mixed material is conveyed to one end of the cylinder and forced out through any

suitable die. The column of clay and vegetable-matter as it issues from the die, is cut into blocks by a buzz-saw, dried by waste heat and fired, the peat serving as an auxiliary fuel.—B. B.

Improvements in Kilns or Ovens for Firing Terra-Cotta and other like Materials. C. D. d'Enghein, A. D. d'Enghein, and S. D. d'Enghein, Belgium. Eng. Pat. 18,281, October 24, 1891.

In these kilns the hearths are at a sufficient distance from one another to leave between them compartments in which delicate articles can be baked. Uniformity of baking is secured by causing the draft to follow two conduits of equal dimensions placed one at each side of the oven. Either wood or coal can be used for heating. The floors of the heating compartments are not horizontal but inclined, an arrangement which facilitates the charging and emptying of the baking compartments.

It is claimed that these kilns effect economy of fuel and of labour, secure uniform baking, do not require close watching, and can, if desired, be charged entirely with glazed goods.—V. C.

A New and Improved Process of Marking Glass by Acid. W. Leader, London. Eng. Pat. 1974, February 2nd, 1892.

This process consists in "steeping brown paper stencils in hydrofluoric acid and pressing on the articles to be marked with heated silver sand."—V. C.

Improvements relating to the Marbling of Enamelled Articles and to Apparatus therefor. G. Güntel Saxony. Eng. Pat. 3024, February 16, 1892.

HITHERTO enamelled kitchen utensils have been given a marbled surface by squirting a liquid upon the surface of the enamel and then shaking the vessel so as to distribute the liquid in lines or veins. This needs care and skill on the part of the operator and at best does not permit of an uniform marbling.

In this invention a plate is used provided with pins or bristles which are dipped in the liquid. From the points of the bristles drops of uniform size are deposited on the enamel in a regular manner. By gently knocking the utensil the drops are caused to run out into veins or lines, and a uniform marbling is thus produced.—V. C.

Improvements in Kilns or Ovens for Burning and Glazing Sanitary Ware and the like. C. Armstrong, Burnley. Eng. Pat. 3586, February 24, 1892.

THE invention relates more particularly to kilns in which sanitary ware is burnt and glazed. In the ordinary kilns sooty matter becomes mixed with the salt and the excessive heat at the roof of the kiln often causes the salt deposited there to liquefy and fall on the goods beneath, producing unsightly blotches. In this invention a midfeather is placed in the fire box projecting downwards into the incandescent fuel, and leaving a space at the back closed by a damper. Instead of disturbing the hardened crust at the top of the fire when the salt is to be deposited (which inevitably produces a cloud of soot) the damper is raised and the salt is introduced at the back of the midfeather where the fire is burning hotly. This prevents the contamination by soot.

To prevent the liquefaction of salt on the roof and the consequent staining or blotching of the goods, air is admitted near the base of the kiln and is carried upwards by flues and discharged along the roof, thereby reducing the temperature at this part of the oven, and thus preventing the formation and adhesion of liquid salt.—V. C.

An Improvement on the Method of Treating Glass Cullet known as "Blacks." J. S. Williams, Brierley Hill. Eng. Pat. 9097, February 29, 1892.

"BLACKS" is the trade term for the glass removed from the blowing irons. Hitherto the adhering rust has been removed from the "blacks" by means of cold acid.

In this invention the acid bath is heated, thereby accelerating the cleansing of the "blacks." The method of heating recommended is by blowing steam into the bath.

—V. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

The New Regulation for the Supply of Portland Cement in Russia. Thonind. Zeit. 1892, 16, 21 and 40.

PORTLAND cement is made either from a calcareous marl or a mixture containing clay and chalk, by burning until friable, and then grinding to a fine powder. The hydraulic modulus, or ratio of the sum of the parts by weight of CaO and (K₂O + Na₂O) to that of the parts by weight of SiO₂, Al₂O₃, and Fe₂O₃ ought not to fall below 1·7 nor to exceed 2·2, for Portland cement.

$$\frac{\text{CaO} + \text{Na}_2\text{O} + \text{K}_2\text{O}}{\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3} = 1\cdot7 \text{ to } 2\cdot2$$

The percentage of sulphuric acid and magnesia should not be greater than 1·75 to 3 in Portland cements ready for use.

The specific gravity of Portland cement must be not less than 3·05.

The cement should not set in less than one hour, or take longer than eight hours. A sieve with 4,900 meshes per sq. cm., should not pass less than 50 per cent., and one with 900 meshes per sq. cm. should pass all but 15 per cent. of residue.

The cement after seven days setting should be able to show a limit of elasticity of 20 kilos. per sq. cm., and after 28 days 25 kilos. per sq. cm. A test piece, prepared with 3 parts sand and 1 cement, should be able to stand, after seven days, 5 kilos. and after 28 days, 8 kilos. per sq. cm.—A. L. S.

The Fifteenth Annual General Meeting of the Association of German Portland Cement Makers. Chem. Zeit. 1892, 16, 371.

At the meeting of the Association held in Berlin on the 26th and 27th of February last, it was stated that there were about 80 members, representing a production in Germany alone of 7,850,000 casks of Portland cement. In the report of the council it was stated that efforts were being made to restrict the use of the name Portland cement to those commercial products which alone had a right to the title. With respect to the magnesia question, two cements had been examined which contained 4·5 and 6·5 per cent. of magnesia respectively, and it would be necessary to ascertain whether they showed a retrograde tendency in course of time. Similar scrutiny was requisite with such cements as contained no admixture of foreign matter nor any abnormal amount of magnesia, but gave unusual results in respect of the loss on ignition, specific gravity, and tensile strength when tested by the standard rules. Brands of cement in the manufacture of which slag was known to figure as a raw material, were also to be examined, lest they should contain slag added subsequently to the manufacture. The question whether it was permissible to add more than 2 per cent. of colouring matter, not with a view of altering the time of setting, but for

bringing the colour of the product to a standard tint, was decided in the negative, it being ruled to be a deception to alter the colour of cement in order to hide the results of careless manufacture. The question as to the permissible

limits of magnesia has not yet been completely decided, and was referred back to the committee. Schumann communicated some results on the influence of oils on Portland cement.

Age of Test Pieces.	Tensile Strength in Kilos. per Square Centimetre.

52 weeks.....	46.2	44.9	..	51.3	35.3	32.0	..	22.0

* Cracked on the outside.

The first series of test pieces were hardened one week in water, three weeks in air at about 30° C., and were then placed in the various liquids mentioned in the table. The test pieces of the second series were differently treated, inasmuch as after the first week in water they were kept for two weeks in air at the ordinary temperature, during which time they were placed in water for half an hour each day. Finally they were immersed in the liquids experimented with as before. The question of the best method of determining the time of setting of Portland cement is now being considered in collaboration with the Director of the Royal Prussian Testing Station for Materials of Construction.

—B. B.

The Action of certain Chlorides on Portland Cement.

Dobrzynski. *Thonind. Zeit.* 1892, 16, 64.

THE author has examined the action of the chlorides of magnesium, barium, sodium, and ammonium upon cement, with the following results. The quantity of water necessary to produce a paste of normal consistence is greater the more difficultly soluble the chloride used. The time of setting is lengthened, in the case of the more difficultly soluble chlorides, as the percentage added is increased. In the experiments on the influence of the various chlorides on the tensile strength, the test pieces were kept in solutions of the same salts at the same degree of concentration as had been used in gauging them. Barium chloride had the most marked effect—a result which the author attributes to the tendency of barium oxide to behave towards the silica and alumina of the cement in the same manner as lime, the resulting compounds however possessing a greater tensile strength. The cement used had a tensile strength of 9.75 kilos. per sq. cm.* at 7 days and 12.83 at 28 days, when tested under normal conditions, that is to say, gauged with three parts of sand to one of cement, using clean water only.

The following results, expressed in kilos. per sq. cm. were obtained when the chlorides above-mentioned were used:—

	Percentage of Chloride.					
	1%	2%	3%	4%	5%	6%
	7 Days.					
Magnesium chloride.	11.0	10.85	11.0	9.25	9.25	8.75
Barium chloride	10.5	10.5	12.6	12.75	12.75	13.25
Ammonium chloride.	10.5	10.25	9.0	8.75	8.75	8.50
Sodium chloride	10.75	10.5	10.0	9.75	11.0	8.6

* To convert kilos. per square cm. into pounds per square inch multiply by 14.2545.

	Percentage of Chloride.					
	1%	2%	3%	4%	5%	6%
	28 Days.					
Magnesium chloride.	13.75	13.5	13.5	11.5	11.0	10.5
Barium chloride	13.5	13.5	14.75	14.75	15.0	15.25
Ammonium chloride.	12.75	12.75	12.0	11.5	11.25	10.75

PATENTS.

A Process or Method of Treating Meerschaum to render it as Porous and as Absorbent in the Manufactured State as in the Natural, and to Adapt it to Various Uses.
J. S. Weingott, London. Eng. Pat. 11,244, July 2, 1891.

THE meerschaum either in the rough state or cut to any desired shape, such as a pipe bowl, which may or may not have been previously polished or waxed in the usual way, is gradually heated so as without cracking to carbonise and blacken it. The operation may be conducted by placing the articles to be treated between layers of dry sawdust (preferably oak) and igniting the sawdust, or in a closed vessel and heating the exterior thereof. The meerschaum is then plunged into melted wax or oil and re-heated, until a deep black colour is produced, after which it may be polished with waxed cloths. It may also be dipped in a solution of pyrogallie acid with a view of neutralising the nicotine from the tobacco; other solutions of similar efficacy may be employed. Meerschaum prepared according to the invention is capable of being used for crucibles, cups and the like.—B. B.

The Manufacture of an Improved Compound for Coating Walls and other Surfaces and for the Production of Casts or Mouldings and for Analogous Purposes.
R. Norwood, Denmark Hill. Eng. Pat. 21,199, December 4, 1891.

THE object of the invention is to produce an adhesive compound similar to that described in Patent 1620 of 1882, commercially known as "alabastine," but different therefrom in respect of the fact that it can be used with cold water instead of hot. One hundredweight of gypsum is calcined, and while it is hot, five to eight pounds of glue dissolved in water are added, and from half a pound to one pound and a half of zinc sulphate or some equivalent substance, the

object being to retard the setting of the glue and gypsum and produce a harder compound. An alternative method consists in adding the glue dry, relying on the moisture liberated from the gypsum during its calcination for the necessary water. The mixture is heated until both the water from the gypsum and that added with the glue are driven off, the dry mass ground and coloured if desired.—B. B.

Improvements in the Manufacture of a Resistible Material chiefly Designed for Building Purposes. H. Hartmann, Mannheim, Germany. Eng. Pat. 2957, February 15, 1892.

MATERIALS such as "lime, trass, cement, and gypsum," with or without gravel or sand, are mixed with metal strips, shavings, turnings, or wire-like particles, and made into a mass with water, the metal fibres more or less uniting or "felting" together and forming a coherent product. It may be used as a building material for ceilings, floorings, walls, &c., either alone or with a core of ordinary cement concrete, the chief strain on the structure being taken by the outer layers containing the metal wires or strips.—B. B.

Improved Artificial Stones. J. S. Holliday, Camberwell. Eng. Pat. 4496, March 7, 1892.

Two compositions are patented, one for the face and the other for the body of the stone. That for the face consists of whiting 0.25, clean Bath stone dust 0.3, Portland cement 0.3, and yellow ochre 0.15 parts respectively. They are mixed together with water to a suitable consistency, and poured into a mould to a depth sufficient for the face of the block. The backing is composed of crushed slag, washed clean, 0.5, crushed granite 0.2, and Portland cement 0.3 parts respectively, and is poured into the mould after the facing has been prepared. The object of the separate facing is to provide a material capable of being carved or similarly ornamented.—B. B.

An Improved Distemper for Walls, Ceilings, and the Like. A. T. Morse, London. Eng. Pat. 5746, March 23, 1892.

FIFTY parts of gilder's whiting, $12\frac{1}{2}$ parts of gelatin, 10 parts of zinc oxide, 1 part of manganese sulphate, 10 parts of terra alba, 12 parts of Paris white, 14 parts of heavy spar, $\frac{1}{2}$ part of salt, 1 part of alum, and 1 part of bichromate of potash, are separately crushed, then ground and mixed together with colours such as are usual in distempers. The composition may be used with hot or cold water.—B. B.

X.—METALLURGY.

Iron Vessels for Molten Substances. Foehr. Chem. Zeit. 1892, 16, 503 and 532—533.

THE iron boilers, retorts, autoclaves, &c., at present obtainable are much more durable than those formerly made; for example, cast-iron dishes for desilvering zinc are now furnished, which will withstand the wear and tear of 150 operations. The cast iron of which these vessels are constructed is very dense and fine grained, and ferro-manganese, ferro-silicon, ferro-chromium, tungsten, and recently also aluminium are added to it in its manufacture. Very frequently the requisite qualities are attained by mixing various sorts of crude iron, the proportions being kept secret. When two samples of cast iron are compared, of the same composition, that having the highest specific gravity will invariably be found the best to withstand chemical influences and high temperatures. The form of the vessel is of great importance, especially when molten substances are suddenly introduced into them. Steel vessels are more liable to crack than those of cast iron, whilst it is difficult to remove a solidified mass from wrought-iron vessels. To avoid unequal strain, the best form is that of a hemisphere, but this form is impracticable, being difficult to empty and to transport, especially with large quantities of material. After mentioning in detail several forms of iron tilting troughs, all of which have disadvantages, the

author describes the following apparatus which was patented by R. Leder (Quedlinburg, Germany). It consists of a cast-iron trough made in two pieces, which are bound together by a riveted wrought-iron band. In the sketch, *d* is the boundary curve of the two halves of the trough.

IRON VESSELS FOR MOLTEN SUBSTANCES.

When, for example, a stream of slag touches the point *a*, the surroundings of this point expand in all directions, and the trough, if made in one piece, generally splits in the direction *a b*, whereas, when it is made in two pieces, the force acts in the direction *a c*, so that, instead of a fracture, the upper rim *b c* of one half takes the position *b' c'*. The composition of the cast iron of which these vessels are made is kept secret. One of these vessels has been daily in use for several years, and is in excellent preservation. An entire waggon weighs about 500 kilos., and holds 1,000 kilos. of slag. They are so convenient for transport that a wide application for various molten substances is considered probable.—A. R. L.

Alloys of Nickel and Iron. H. Wedding. Verhandl. d. Vereins. z. Beförder. d. Gewerbl. 1892, 52.

FOR general use the alloys should contain but little carbon, less than 0.5 per cent., otherwise they are difficult to work, the amount of nickel should not exceed 5 per cent., otherwise the limit of elasticity is insufficient, and for practical purposes the cost must be kept down, in view both of the amount of nickel used and the difficulty of working. To prepare nickel iron alloy, a mixture of ore containing iron and nickel oxides may be reduced in a blast furnace, but the crude alloy thus obtained is not suitable for the preparation of a malleable alloy (*i.e.*, one poor in carbon). According to Gautier, on refining, nickel oxide is produced, which remains dissolved in the iron and causes it to be brittle.

In order to obtain a malleable alloy, metallic nickel must be added to the fluid malleable iron. The metal should be free from arsenic and sulphur. The alloy is not a chemical compound, but only a mechanical mixture. The addition of aluminium is useful. Experiment must determine how much manganese on the one hand, or magnesium on the other, is necessary to remove the oxygen. The required carbon is best introduced directly.

Further particulars as to the details of preparation and best composition of alloys are at present wanting, but it is hoped that further experiments will remedy this.

—A. L. S.

The World's Production of Gold. Eng. and Mining J. 53, 1892, 272.

BEGINNING with the older gold-fields of the world, California in all probability made about the same out-turn in 1891 as in the previous year, but the mines of Deadwood, South Dakota, have made an increase, and there has also, without doubt, been an increase from the silver mines the ore of which carries some gold. It is estimated that the total production of gold in the United States in 1891 had

amounted to 33,250,000 dols., against 32,845,000 dols. in 1890, as reported by the Director of the Mint. Australia will in all probability show about the same yield in 1891 as in 1890, for although there has been a falling-off in the product of the Mount Morgan mine, the great gold producer of Queensland, and perhaps also in New South Wales, the returns from Victoria show an increase of 37,216 oz., which will do much to make up for the deficiencies of the other colonies, not in any case likely to be large. The latest statistics from Russia, those for 1890, show an increase of over 75,000 oz. over the production of 1889, and although the returns for 1891 have not yet been compiled, it is officially reported that all indications point to another notable increase.

In the Transvaal the year 1891 was a phenomenal one, the output of the Witwatersrandt mines having amounted to 729,223 oz. against 494,801 oz. in 1890. The regularity of the advance in the yield of these mines month by month for the past four years, or since they were first opened, leaves no doubt that their maximum capacity has not yet been reached. Indeed the year 1892 has been commenced by a remarkable increase, the production during the month of January having amounted to 84,560 oz. against 80,312 oz. in December, this having been the greatest output in any one month in the history of the district. The production of the four principal gold mines of Mysore, India, which practically represents the total gold output of that country, was also considerably greater in 1891 than in 1890, amounting to 130,140 oz. against 104,500 oz. Here, too, the output has shown such a regular expansion during the past three years that it is probable that the climax has not yet been attained, and a steadily increasing yield may be expected from this source.

According to statistics, the United States, Australasia, Russia, Africa, and India produced in 1890 a trifle more than 83 per cent. of the total amount of gold produced in the world. In 1891 each of these countries or natural divisions made an increased output, with the possible exception of Australasia, and in the case of Africa, Russia, and India the increase was large and important.

But there is every reason to expect that new deposits of auriferous gravel and auriferous quartz lodes will be found within the next few years, particularly in the United States, Africa, and Siberia, while it is certain that the extensive and rich beds of gravel in Brazil will not remain unworked much longer. The vast expanse of country forming the north-western portion of the United States has by no means been thoroughly prospected, and new gold mines are constantly being found and opened there. Africa, an unexplored country, bids fair to yield a constantly increasing amount of gold. Pioneers are just going into Mashonaland and Matabele-land, and the reports that they send out are generally favourable. Eastern Siberia is also a land of great promise. Only within the past month has come news of new gold fields at Nertschink, in the valley of the River Boon, which are said to be rich. In Brazil there are immense beds of auriferous gravel, which can be worked without difficulty. No doubt is felt that the production of gold in the world will show as great an increase in the present decade as it did from 1880 to 1890, when it rose from 160,152 kilos. to 174,556 kilos.—W. S.

The Basic Bessemer Process applied to the Metallurgy of Lead. Rev. Univ. des Mines et de la Met. Jaouary 1892; Eng. and Mining J. 53, 1892, 431.

DR. ROESING, formerly director of the Friedrichshütte works in Upper Silesia, has applied the basic converter to the treatment of base bullion. By this process the lead is oxidised to litharge, which is then reduced by carbon or by galena. A part of the lead may be desilverised by zinc and refined in the converter. The following processes constitute the new system: A. treatment in the converter; (1) of base bullion for pure litharge and enriched lead; (2) enriched lead for impure litharge and lead-silver; (3) desilverised lead for refined lead. B. reduction of the pure litharge by carbon for merchantable lead. C. treatment of the galena with molten litharge for base bullion. The most interesting and most important of these innovations is the treatment of the base bullion in the converter.

Calorific calculations having led to the anticipation of favourable results, experiments were made with this process in the laboratory in quantities of 500 grms.; then with charges of 6,000 kilos. in a Thomas converter at the Friedrichshütte in Upper Silesia. The method presented no difficulty; the charge of 6,000 kilos. of base bullion was blown for 15 minutes with air pressure of $1\frac{1}{2}$ atmospheres. The lead had been heated previously a little above its melting point. The litharge formed had a temperature of more than $1,200^{\circ}$ and was very fluid. It crystallised in mass on cooling without formation of any amorphous litharge, and fell in scales. The silver contents of the litharge were 0.0036 per cent., but could be diminished in regular working.

In treating poor, impure and zinciferous lead the refined lead obtained in a few minutes was of excellent quality and the following composition: Lead (by difference), 99.9934 per cent.; antimony, 0.0007 per cent.; arsenic, 0.0005 per cent.; copper, 0.0013 per cent.; iron, 0.0022 per cent.; zinc, 0.0015 per cent.; silver, 0.0004 per cent.

In consequence of the great increase of temperature in the converter during the blowing, new charges may be worked immediately without reheating the vessel, so that there is no delay in the process. In regular operation it would possibly pay even to utilise the heat obtained in the converter for the fusion of the lead.

The basic lining of the converter stood perfectly. The engineers of the Friedrichshütte steel works declared "that they are satisfied that the basic lining will last better in treatment of lead than in the manufacture of steel."

The impurities of the lead (zinc, arsenic, and antimony) are removed in a more rational manner than in the common process since the blast acts uniformly throughout the mass and not merely upon the surface of the bath; the latter is to-day, purified first, then uselessly oxidised, while the impurities contained in the lower strata of the metal are a long time withheld from the action of oxygen. There results therefore an oxidation, which is superfluous and injurious to the lead. In the new process it is necessary to take into account the reduction in the expense of treatment and the loss in the working of intermediary products. As for the loss in blowing there is produced naturally in that operation very thick lead smoke, but as it is of very short duration, the amount is small and it can be easily recovered because it is not mixed with combustion products. In this process there is a saving in comparison with cupellation, according to the calculations made at the Friedrichshütte, of 18 marks and 94 pfennig (4.50 dols.) per 1,000 kilos. of base bullion. As for enrichment of the lead it is recommended not to carry it too far at once, but rather to interrupt the blowing at intervals and unite the lead of several charges which can be submitted to a new operation for enrichment.

In the experiments at the Friedrichshütte with base bullion containing 0.0425 per cent. of silver, lead assaying 0.673 per cent. silver has been obtained as a maximum and condensed fumes with 75 per cent. lead and 0.0086 per cent. silver.

The litharge obtained is very liquid and can be reduced in a very simple manner by pouring it on a bed of incandescent carbon in a special furnace by which it is immediately reduced. The same furnace may be employed for the treatment of the galena. The latter is comminuted to fine grains and heated to the point where roasting commences. If the liquid litharge is spread on this galena it is rapidly decomposed with the evolution of sulphurous acid gas which is mixed neither with an excess of air nor with combustion products, and consequently can be recovered easily. The rapidity of the decomposition of the litharge by carbon or by the galena permits of a large production in small apparatus, and the consumption of fuel amounts only to that required in the preliminary heating. The amount of labour necessary and the loss in metal are both very small.—W. S.

The Passive State of Iron and Steel. Part II. Thos. Andrews. Proc. Royal Soc. 50 [303].

In Part I. of this research (Roy. Soc. Proc. 48, 116; this Journal, 1890, 951), the author showed the influence of

magnetisation on the passive state of iron and steel, and now the results of a further study of certain temperature and other conditions affecting the passivity of these metals in concentrated nitric acid are given. The experiments of Series III. in this paper relate to the effect of temperature, and the observations of Series IV. refer to the influence exerted by nitric acids, of various degrees of concentration, on the passive condition of iron and steel.

SERIES III.

Effect of Temperature on the Passivity of Iron and Steel.—The bars selected for these observations were unmagnetised polished rods, which had been previously drawn cold through a wortle; a pair of bars of each metal were cut adjacently from one longer bar, and then placed securely in the wooden stand W; each bar was $8\frac{1}{4}$ ins.

Fig. 1.

long, 0.261 in. diameter. The U-tube, containing $1\frac{1}{4}$ fluid ounce of nitric acid, specific gravity 1.42, was rigidly placed in an arrangement as shown in Fig. 1. One limb, A, was surrounded by a tank containing water, the other limb, B, by a tank of the same capacity, containing powdered ice; the arrangement was such that the water-tank could be heated by a Bunsen burner, and its tem-

Fig. 2.

perature slowly raised, whilst the ice-tank was kept full of powdered ice. A non-conductor of wood was put between the ends of the two tanks so as to prevent the melting of the ice; the bottom or bent portion of the U-tube was also enclosed in a thick non-conductor of wood. A thermometer, T, was placed in the water-tank. The bars were in circuit with the galvanometer, and soon after immersing them in the nitric acid heat was applied to the water-tank, and the temperature of the nitric acid in that limb of the U-tube slowly raised to the temperatures required, whilst the acid in the other limb of the U-tube was meanwhile maintained at a temperature of 32° F. The arrangement will be understood on reference to Fig. 1. Current between two bright "passive" bars of the same composition, one in warm, the other in cold, nitric acid, sp. gr. 1.42. The electro-chemical position of the bars in the warm nitric acid was positive. The experiments show that the wrought iron was less passive in the warm nitric

acid than the soft cast steel; the average E.M.F. of 94 observations with wrought iron was 0·030 volt; whereas in the case of the 94 observations on cast steel the average E.M.F. was only 0·010 volt. The behaviour of the steel, under the conditions stated, was more irregular than that of the wrought iron.

In the whole of the series of experiments the nitric acid was raised to a temperature of 175° F.; the cold nitric acid in the limb of the U-tube A remained perfectly colourless, and the steel or iron therein absolutely passive; but the steel or iron in the warm nitric acid in tube A commenced to be gradually acted upon as the temperature increased, a pale yellow tint beginning to appear in the solution in the tube A shortly after commencement. When the temperature of about 170° to 175° F. was reached, a faint evolution of gas in the form of bubbles was manifest, adhering to the steel, in the warm tube only. No powerful solvent action or violent evolution of nitric-oxide gas, however, occurred in any of these experiments even up to the temperature of 175° F., and these experiments were not continued beyond this temperature. These results show that iron or steel does not fully lose its passivity up to a temperature even of 175° F., though the passivity is shown to have been considerably modified by temperature only. The critical point of temperature of transition from the passive to the active state is therefore higher than 175° F., and is shown in the experiments of Part I., Series II., Table II., to have been about 195° F. (this Journal, 1890, 951).

SERIES IV.

The Passivity of Iron and various Steels increases with the Concentration of the Nitric Acid.—Schönbein considered that "by immersing an iron wire in nitric acid 1·50 sp. gr., it became likewise indifferent to the same acid of 1·35 sp. gr.," and to all outward appearance this is so. Scheurer-Kestner considered that the passivity of iron was not dependent on the greater or less degree of saturation of

the acid. The author, however, ascertained by the delicate electro-chemical mode of experimentation employed, and hereafter referred to, that the passivity is materially influenced according to the concentration of the nitric acid. The following experiments indicate that the property of passivity in iron is not absolutely fixed or static, but that its passivity is modified to a certain extent in relation to the strength of the nitric acid used. The *modus operandi* was generally similar to that previously employed. Pairs of unmagnetised polished steel bars, 6 in. long and 0·310 in. diameter, each pair being of the same kind of steel, and cut adjacently from one longer bar, were placed as before in the wooden frame W (Fig. 2), and then instantly and simultaneously immersed in nitric acids, of two different degrees of concentration, contained in the U-tube arrangement, one limb of the U-tube containing red fuming nitric acid of sp. gr. 1·50, the other containing nitric acid of sp. gr. 1·42, circuit being made through the galvanometer in the usual manner. The results, the average of repeated experiments in each case, are given in Table III., and show that the passivity of iron increases considerably with the strength of the nitric acid.

The steel rods selected for this set of experiments were of the kinds given in Table IV.; they were drawn cold through a worte, and were of the general physical properties and chemical composition given in Tables IV. and V. The reduction of the E.M.F. towards the close was probably owing to partial diffusion between the two acids of different concentration. The above results show that wrought iron was less passive in the weaker acid than most of the steels, the soft Bessemer steel being found similar in passivity to the wrought iron. The average E.M.F. was as follows:—With wrought iron, 0·054 volt; soft cast steel, 0·028 volt; hard cast steel, 0·036 volt; soft Bessemer steel, 0·059 volt; tungsten steel, 0·039 volt.—W. S.

Parting Bullion. F. Gutzkow. Eng. and Mining J.
53, 1892, 497—498.

It is stated that the process works regularly and with best success, the refining costs being 0.35 cents per ounce. Considering that in Argentine, Kansas, the wages of the men employed at the plant are 3 dols. and 4 dols. per day, and the cost of sulphuric acid $1\frac{1}{2}$ cents per pound, elsewhere refining may doubtless be done at 0.25 cent per ounce. Parting charges average 1 cent per ounce in the eastern half of the United States and 2 cents per ounce in San Francisco, so the pecuniary advantage is apparent. In the following is described the plant and the operations of one of those small establishments having a maximum capacity of parting, say, 6,000 oz. of doré in the day-shift by the author's improved process. Fig. 1 shows the plant in top-view and Fig. 2 in section.

1. *Parting.*—It is assumed that the bullion is of the common high grade character, containing 90 per cent. or more of silver. It may be placed in the kettle in the shape in which it leaves the mill or smelting works; that is, as retorted amalgam or in large and irregular bars as they are ladled from the cupelling furnace, or in slabs of more uniform size and thickness if the bullion is re-melted in order to charge it to the parting works by weight and assay. The charge may vary according to local convenience, the maximum being about 400 lb. of doré. The commercial sulphuric acid is admitted into the kettle by gravitation from the wrought-iron drum which serves as a reservoir, and ought to be large enough to hold the 50,000 to 60,000 lb. of acid shipped in a "tank car." One or more old steam boilers may be arranged for this purpose, and the acid may be raised into them by exhausting the air therefrom by a steam jet. The consumption of sulphuric acid of 66° B. need not, and after some practice will not, exceed materially the stoichiometrical proportion, which is 1 lb. of acid for one of silver, as all surplus acid evaporated or required for dissolving the silver sulphate is regained and utilised in the course of the process.

For a beginner it is advisable to employ between the kettle and acid reservoir a small cast-iron tank as an intermediate reservoir in which the acid required for the charge of bullion under treatment may be measured off.

It will be noticed in the figure that the usual half-globe shape of the parting kettle is discarded, but a flat bottom with a pocket or well in the centre in the shape of a spherical segment is used. To gain more capacity for equal height is one reason for this construction, but the most important one is that the bottom can be reached everywhere by a straight-edged stirrer or paddle, and, practically speaking, that every particle of gold can be scraped into the pocket and be taken therefrom with a ladle. This is not possible in a round-bottom kettle in the position in which the refiner has to work.

The dissolving of the stated maximum charge takes from four to six hours, according to the heat employed. When the larger half of the bullion appears to be dissolved "mother-acid" is added from 7, a pitcher or two at a time, until the charge is completely dissolved.

The fire is now moderated and the kettle is gradually filled with mother-acid within an inch or two from the top. These gradual additions are regulated by the temperature of the solution in the kettle, which ought to be so that only faint fumes are discernible. If the fuming stops entirely it signifies that the temperature has become too low, and that silver sulphate may separate. The gold ought to keep its bright colour during this operation, which presents no difficulty. At larger works, for instance at Argentine, the mother-acid is lifted by steam power, but lifting by hand is sufficiently convenient for the small plant under description. The well-stirred contents are now ready for settling, and the fire is still further moderated. Ten minutes is all the time required and given for settling, that is, for obtaining a perfectly clear solution of silver sulphate, which may be safely siphoned off the insoluble residue without carrying any gold along. This rapid settling is due to the change of the iron sulphate formed during dissolving from a yellowish slowly subsiding salt into a greenish flocculent compound, which carries all suspended matter readily to the bottom. The solution is now siphoned into the open cast iron pan 6.

A $\frac{3}{4}$ -in. gas pipe, which is suitably bent and ends in a "return elbow" resting on the bottom of the kettle, is used as a siphon. The proximity of 6 to 5 has the advantage that only a short siphon is required.

2. *The Gold.*—The residue in the kettle contains, besides silver solution, the gold and the insoluble sulphates of iron, lead, antimony, mercury, &c., together with sulphate of copper, if the bullion contained more than a certain amount of this, and sulphate of silver if the heat has not been well regulated. It is ladled into a portable copper kettle (the solution settling therein is poured back into 5), which is carried to the lead-lined tank 8. Here it is emptied, and the contents are boiled with water until the sulphates soluble in water, viz., those of iron, copper, and silver, have dissolved. The fairly settled solution runs on the "gold filter," which is a piece of cotton cloth spread over a false bottom in the tank 9. The filtered solution finds yet a chance to settle underneath the false bottom and overflows into the "silver filter" 10. The gold is brushed and washed through a pipe toward which the bottom of 8 pitches from all sides into a large earthen dish resting on the cloth of 9. In this dish it is stirred with hot water and decanted over the cloth until the insoluble sulphates have been washed off and the gold is left bright and clean. It is then scraped into a smaller dish and delivered to the superintendent to be melted in the assay office when sufficient weight has been accumulated for a commercial bar.

Of course it will be just as well or better to deliver the copper kettle with its acid contents to the care of the superintendent, and to make one job of the washing of the several batches of gold when there has been enough collected. The cloth on 9 is scraped and sponged into an earthen jar, and, after settling, is decanted back on 9. The stuff collected is occasionally dried and melted with the fluxes from melting the gold and silver into a button. The appearance of the latter decides whether it can go at once into the parting kettle or is to be cupelled with addition of some lead in a bone-ash cupel, stamped into a worn-out crucible, and heated in the melting furnace.

3. *The Silver.*—The great bulk of the silver is in the hot solution which stands in 6, about 6 in. high, when the plant works to its maximum. Steam is now blown in and the solution is tested for sufficiency of dilution in the manner fully described in my previous article. The diluted acid, which is caught in the leaden condenser-pipe leading from 5 to the chimney, may occasionally be mixed in for utilisation when the steam has raised the temperature high enough to allow such addition without causing a precipitation of silver sulphate. The solution is now allowed to cool over-night.

In Argentine, water cooling is used, but it is hardly necessary in San Francisco. In the morning the mother-acid is allowed to run off into the cast-iron reservoir 7. Through an iron pipe toward which the bottom of No. 6 slopes, the crystals are detached by an iron shovel, and are thrown on the false bottom of the draining-box 11, which runs on wheels and has been moved to 6. They are sprinkled with water, and the first drainage, down to a certain specific gravity, is run back into 6. The box 11 is then moved into the position shown in the Figure. Here cold water is allowed to percolate through the crystals until the free acids and the sulphates of iron and copper are removed. The liquid runs on the silver filter 10, where all silver which it holds in solution is retained, and it escapes finally through the pipe 12. The silver filter is a lead-lined box provided with a false bottom. It is filled to about 6 in. above the false bottom with precipitated copper. The silver separates on the top of the copper as a spongy sheet, a corresponding amount of copper being dissolved. Once or twice the sheet is loosened and turned in order to expose what copper may cling to it to the first action of the silver liquid entering. When the sweetening of the crystals has been finished and the crystals have been removed from 11 for further treatment, the silver separated in 10 is thrown on the false bottom of 11, a shovel of crystals is added, and 11 is filled with hot water and left at rest. By the time that 11 is again required to receive another batch of crystals from 6 all copper which the silver sponge may have still

retained has been dissolved, the liquid is run on 10, and the silver is left in 11 to be mixed with the new charge of crystals. In practice the total amount of silver thus

rendered metallic does not exceed 3 per cent. of the whole, as the crystals of silver sulphate are only slightly dissolved by cold water.

GUTZKOW'S PARTING PROCESS.

ARRANGEMENT OF PLANT.

BULLION PARTING PLANT.

1, drying pan; 2, melting furnace; 3, dust chamber; 4, chimney; 5, parting kettle; 6, crystallising pan; 7, reservoir for mother-acid; 8, lead-lined tank for boiling gold; 9, do. for "gold filter"; 10, do. for "silver filter"; 11, do. for draining crystals; 12, outlet of all liquids; 13, reservoir for commercial acid; 14, hot water tank.

The sweetened crystals from 400 lb. of bullion, which measure about 2 cb. ft., are now thrown on the drying-pan 1. When dry they are mixed with 5 per cent., more or less, of charcoal, the weight of the charcoal which is necessary being ascertained approximately from the known weight of the bullion which has furnished the batch of crystals under treatment. The mixing is done on the pan 1 itself and the mixture is at once fed into the hot crucible in the melting furnace 2. The silver sulphate is reduced at a very low temperature, that is, at just red heat, into metallic silver, carbonate and sulphurous gases being evolved and escaping without causing any trouble whatever, every trace of these gases having been removed by the time the temperature of melting silver is reached. The surplus of charcoal is finally lifted off the molten silver and reserved for mixing with the next charge of crystals. The silver is cleared by borax and toughened with nitre until the so-called "boiling" indicates that spitting needs to be apprehended no further. After cooling to the proper temperature it is ladled into moulds, a little assay bar being cast from the first and last ladle, and the crucible is again charged with the mixture of crystals and charcoal.

Those who are familiar with the author's old San Francisco process from its description in "Percy's Metallurgy" will notice that the treatment of the silver as here described contains three essential novelties, namely: First, the dilution of the original silver solution by steam, which forms the claim of his patent, and enables him to work with only one-third of the volume of "mother-acid" previously employed. In addition, it dispenses with certain cumbersome apparatus. Second, the desilverisation of weak silver solutions over a bed of precipitated copper, which replaces their storing in capacious lead-lined tanks for re-utilisation or for treatment with copper, or iron, or salt. Anybody who knows of the difficulty of getting a plumber who understands lead burning with the hydrogen flame to an out-of-the-way place, or has heard of the lead-burners' union, will appreciate the reduction of size and number of lead-lined tanks. The few small

tanks used are shipped ready-made from Chicago. Third, the direct reduction in the crucible of the silver sulphate with charcoal. His former practice had been to reduce the crystals to the metallic state by percolating them in the draining-box 11 with a hot solution of ferrous sulphate. The ferric solution which was thus formed was made again ferrous by metallic iron and used over again. The silver was sweetened with hot water, then dried and melted. The advantages of the new method need hardly be discussed.

4. *The Copper.*—The liquid which flows from 12 removes all the copper which the bullion did contain, and all that which has been dissolved in the silver filter 11. In parting works, which treat only high grade bullion, the weight of the copper thus escaping is so small that it hardly pays for its recovery. The liquid from 12 may run to waste, and the copper in the silver filter be replenished by preparing occasionally a quantity of it at the works by dissolving bluestone in 8, and precipitating the solution by iron in 9, or by buying some in the market. When, however, the bullion contains a larger percentage of copper than can be economically neglected, the liquid issuing from 12 is carried in the usual manner through troughs or other vessels containing old iron.

This process is common enough, but it requires some judgment. It ought to be known that precipitated copper ought never to be exposed to the atmosphere before sweetening, because certain basic salts of iron are formed which are insoluble even in boiling diluted acid, and that in an acid ferrous sulphate solution, even in this absence of iron, a continual consumption of acid takes place, because the ferric sulphate formed by the atmosphere absorbs more acid than the ferrous sulphate from which it was generated continued, and, lastly, that no copper precipitated from cold or merely warm solution is fit for sweetening by filtration, on the large scale at least, before it has been violently boiled in acid water and thus has been made dense. For parting very low grade bullion with 30 or more per cent. of copper,

the author modifies the process of dissolving in the kettle 5 in a novel manner which he may publish at some future occasion.

5. *The Lead*.—It has been said already that the lead sulphate is washed from the gold by decanting. The amount of lead in the residue taken from the parting kettle is, however, very small, much less than is generally assumed, and almost *nil* when, as ought to be done in larger establishments, the gold is subjected to a second boiling with sulphuric acid. The sulphuric acid process in this surpasses the electrical method of parting. By the latter a number of substances, among which are quite unusual ones, as, for instance, tellurium, separate with the gold and have to be removed by special treatment. The vaunted simplicity of the electrical process may well be questioned when it is known that it includes a boiling of the gold with nitric acid with all the appliances and operations of a miniature parting plant working by that old-fashioned process. In the sulphuric acid process, at least by his method, all the gold in the bullion which is placed into the parting kettle in the morning is delivered in the evening as a fine and tough bar, except what traces cannot be scraped from the kettle, and what the sponging of the gold filter may have removed. The principal part of the lead in the bullion, provided the latter contains of it only a few per cent., is dissolved in the hot silver solution.

In the old style of parting this solution is poured into a tank containing water and copper, and every trace of lead sulphate consequently intermingles with the silver to be removed therefrom by fluxing and toughening. By the author's modification the lead sulphate separates on diluting the solution by steam, and has subsided by the time the formation of crystals commences. It coats, therefore, the crystals where they have touched the crystallising pan. The following method for removing the lead sulphate is employed, whenever the character of the bullion makes it necessary to do so:—The crystals of silver sulphate are not directly shovelled from 6 into the draining-box 11 as described above, but are thrown into a small lead-lined tank filled with water, are stirred therein, and finally taken out with a wooden shovel and thrown into 11. The powdery sulphates of lead, antimony, &c. are very readily washed off the heavy, hard, and large-sized crystals. What is left behind in the wash-tank is heated by steam, the solution is run over the silver filter, while the residue of lead sulphate, &c. is made metallic by adding some iron, and finally washed, melted, and cupelled.—W. S.

The Gold and Platinum Industry of the Ural. Annales des Mines, 18, 537, and Eng. and Mining J. 53, 430.

The auriferous deposits of the Ural have been classified by Karpinsky into primary and secondary groups. In the former gold is found either in quartzose vein-stuff, or interspersed through the mass of crystalline rocks, such as diorite and serpentine, while the secondary deposits are auriferous sands, situated either immediately above the primitive deposits, or transported to and re-arranged at some distance from the point of origin. Platinum is only found in secondary or alluvial deposits. The primary gold deposits of the Ural are very numerous, four groups of them being actually worked—namely, those of Berezowsk and Goroblagodask, of the district of Miask, of the Baschkir territory, and of the Orenburg Cossacks.

The Berezowsk deposits, which are the only ones that have been systematically developed to any extent, are included in an area of about 22 square miles, in which the prevailing rocks are schists penetrated by numerous veins or dykes of a fine-grained granitic rock containing pyrites known as beresite, varying in thickness from 12 ft. to 120 ft. and upward, many of which extend beyond the limits of the mining region. The beresite dykes are traversed by numerous fissures filled with quartz, forming veins varying in thickness from about 10 mm. to 70 mm., or, on an average, 30 mm., having a general east and west course, often uniting into groups but never becoming parallel to the enclosing dyke. Sometimes, but rarely, they pass from the beresites into the neighbouring schistose rocks. The

vein-stuff, as well as the rock, where most auriferous, is rusted from the decomposition of pyrites; the best mines yield from 1 to 1½ oz. per ton, 10 grms. (about 7 dwts.) being considered as the lowest workable limit. The pyrites is often much richer than the quartz, in some instances averaging up to 6 or 7 oz. per ton. Below the level of decomposition of the pyrites into gossan, or as it is locally called, *krassiks*, the gold appears to be entirely contained as sulphide.

The secondary auriferous deposits, although called sands, are almost entirely clays, pure or somewhat sandy, and enclosing rolled masses and blocks of many different rocks. They are found throughout the whole Ural region over a length of more than 500 miles, having filled the valleys and forming marshy plains on both slopes of the chain, the larger development being, however, on the eastern side.

Gold is found in the alluvium in particles of all sizes up to large nuggets, accompanied by many other minerals, such as palladium, platinum, osmiridium, native copper, diamond, cinnabar, iron pyrites, magnetite, chromite, specular iron ore, rutile, brookite, anatase, corundum, garnet, and quartz. Speaking generally, the deposits associated with rocks containing hornblende and augite are richer than those in which granite and gneissic rocks prevail.

The auriferous beds vary in thickness from about 1½ ft. to 3½ ft., in breadth from 60 ft. to 150 ft., and exceptionally to about 300 ft., and in length from 60 ft. or 80 ft. to 1,500 ft., the direction being generally parallel to that of the chain. The most extensive deposits are those of Balbuk, 2½ miles, and Stolbuk, 3½ miles long. The sterile covering or over-burden is usually less than 13 ft., although exceptional deposits have been found at 60 ft. and even 130 ft. below the surface. The cover very frequently forms peat bogs. The amount of gold varies from 12 to 39 grs. per ton of sand, although occasionally it is double or even four times the latter amount.

Platinum has not up to the present time been found except in alluvial deposits, in which it is always associated with gold; sometimes the latter predominates, and the platinum may not exceed 1 per cent. of the product. On the other hand, gold may at times be almost absent, and the deposits in which this condition prevails, although less abundant, are those of most value. They are confined to districts of Nischne, Tagil, Goroblagodask, and Biseik. In the first of these localities they extend for about 25 miles to the south of the village, and from the associated minerals, such as olivine and chromite, they appear to be derived from the waste of a mass of serpentine known as Mount Solvaïska or the White Mountain. The platinum is found in grains and nuggets, the largest of the latter weighing about 320 oz. The yield varies from 39 to 195 grs. per ton. The richest deposits, those of the Martiane River, are from 13 ft. to 16 ft. thick, and are covered by 60 ft. or 70 ft. of overburden, chiefly consisting of clay. The conditions of occurrence in the other localities are similar to those described above, except at Goroblagodask, where the bed rock of the alluvia is limestone, but outcrops of porphyry and serpentine are found in the vicinity.

The gold deposits are partly the property of the Crown or its lessees, and partly of private individuals, but in the latter case there is often a reservation of minerals which are subjected to special royalty rents. The rate paid by the Crown lessees is from 8½ per cent. to 20 per cent., in addition to which a 3 per cent. tax is levied on all gold produced in any of the mines, the product being compulsorily saleable to the State. Platinum working, on the contrary, is free from all taxation, and the government monopoly of refining, which was kept up for a time, having been abandoned, the product is mostly placed in the London and Paris markets.

In working the alluvial deposits two methods are followed. In the first the plant and apparatus are provided by the ground owner, who hires labour and directs the operations, either personally or by deputy; while in the second a system of tribute is followed, the ground being let to free workmen or *starateli*, who provide everything necessary for working, and deliver the produce at a fixed rate to the proprietor. This price may vary with the difficulty of working, from 9 dols. to 10·50 dols. per oz.; but in all cases

the prime cost in the proprietary workings is higher than in those of the free labourers, who are able to handle, to a profit, stuff with from 8 to 10 grs. of gold per ton. Platinum sands are considered poor when containing less than 45 grs., and rich when above 180 grs. per ton. The lowest profitable limit seems to be about 39 grs.

The platinum workings of Avrorinski are at present the most important operations of their class. The deposits, from 13 ft. to 16 ft. thick, lie upon a conglomerate of serpentine, are covered by nearly 80 ft. of dead ground, and extend for about $1\frac{1}{2}$ miles, with a breadth varying between 70 ft. and 250 ft. The average yield is about 87 grs. of platinum minerals per ton, but in places it goes up to 20, 30, or even 50 times as much. The working is entirely subterranean, small pits 70 ft. to 80 ft. apart being sunk to the deposit, and the material, being drawn to the surface by windlasses, is washed in the ordinary Siberian frame at the mouth of the pit. About 400 hands are employed, the work going on night and day.

The crude platinum contains about 1 part in 4,000 of gold, which is separated by amalgamation and washing with water in large capsules. The final product contains 90 per cent. of platinum. The whole of the gold produced in the Ural and Siberia is sent to the Government assay office at Ekaterineborg, where it is melted and cast into bars, the assay of which forms the basis of final settlement between the Government and the miners.—W. Improvements in the Extraction of Precious Metals from Ores. W. T. Rickard, London. Eng. Pat. 6479, April 15, 1891.

THE finely pulverised ore, either raw or roasted, as the case may be, is charged into an iron tank with a semicircular bottom, and is mixed with water to a thin pulp by means of a revolving horizontal shaft carrying iron discs, set at an angle. The temperature is then advantageously raised by steam to about 180° F. and, while the discs are revolving a solution of acid mercury sulphate and a small quantity of the metal are added to the pulp. After half an hour the rate of rotation is diminished so as to allow the amalgam to settle, whilst the tailings are washed away by a stream of water; or the mass is run into a settling tank of similar construction to the above but furnished with amalgamated copper discs instead of iron ones; or the usual course of running over amalgamated copper plates with the ordinary mercury traps may be pursued.

Wooden tanks and scrap iron may be used instead of iron tanks for the amalgamation. The evolution of hydrogen is regarded as an important auxiliary. It is claimed, owing to the precipitation of metallic mercury within the mass, that even the finest particles of gold and silver are amalgamated by the atom treatment. The precious metals are recovered in the ordinary way from the amalgam.

Refractory ores are first roasted in a furnace constructed with a number of superposed hearths, with a fire-grate at one end of the lowest hearth, whilst the space above the uppermost hearth communicates with the first of a series of settling chambers, having the inlets and outlets alternately at the top and the bottom; hence hot gases in traversing them have to assume a zig-zag course, which facilitates the deposition of suspended matters. In the side of the furnace doors are provided for each chamber and hearth, and the latter have also an opening in the middle of the bed,

through which ore settling on them can be discharged into a truck placed beneath the lowest hearth. The pulverised ore is fed from a hopper fitted with a screw or other regulating appliance, through an elongated horizontal pipe, into the throat of the furnace, where it encounters a blast of hot air, and is projected on to the end edge of one of the hearths. By this means the ore is scattered, kept in motion, and carried along by the gaseous current, and a suitable temperature being maintained the desired oxidation ensues.—D. A. L.

New or Improved Metallic Alloys. S. Pearson and J. H. Pratt, Birmingham. Eng. Pat. 8137, May 12, 1891.

PATENTEES make various alloys by any means, but ordinarily by first melting either copper and nickel together or previously prepared copper-nickel alloys and then mixing in the zinc. The proportions are varied according to the character of the product required, but the following are the proportions preferred:—

Nickel.	Copper.	Zinc.	Nickel.	Copper.	Zinc.
Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
$\frac{1}{2}$	59 $\frac{1}{2}$	40	6	46	48
1	58	41	7	43	50
2	56	42	8	42	50
3	54	43	9	41	50
4	51	45	10	40	50
5	49	46			

The first three yield superior brass or bronze, giving a smoother surface than ordinary brass when cut, filed, or turned; the fourth, fifth, and sixth are similar but harder, whilst the subsequent mixtures exhibit a progressive hardness and are sufficiently white to replace German silver.

To give the alloys a fine close grain and to render them more malleable and ductile they are vigorously stirred when in a molten state with a mixture of 100 parts of manganese dioxide, or carbonate, 50 parts of borax, and 25 parts of potassium or sodium nitrate, or an equal weight of carbon, using $\frac{1}{2}$ to 3 oz. of this mixture for each pound of alloy. Whereas an addition of $\frac{1}{4}$ to 1 per cent. of aluminium to the alloys is made when greater tensile strength is required.

All these alloys may be rolled and drawn hot.—D. A. L.

A Process for Extraction of Antimony from its Ores, and Separation of other Metals therefrom. A. W. Warwick, London. Eng. Pat. 8415, May 15, 1891.

By this process the finely pulverised ore is agitated and heated with a solution of an alkaline sulphide or hydroxide, and the filtered liquid is either acidified, to precipitate the antimony as sulphide from which the metal is recovered in the ordinary way, or the liquid may be treated electrolytically and the antimony deposited from it directly as metal.

—D. A. L.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

The Siemens Electrolytic Process for the Extraction of Copper from the Ores. Eng. and Mining J. **53**, 1892, 327 and 329.

COPPER has hitherto been extracted from its ores in the electrolytic way by using as anodes either plates of impure copper or copper matte. The copper was then dissolved from the anode and precipitated galvanically at the cathode. Only a part of the electric current was utilised, however, for dissolving the copper, the solution soon became poor in copper, and had to be replaced by a new solution, the formation of which from the ores was attended with expense and difficulty. Moreover, the use of copper matte for the anodes required a previous smelting of the roasted ore, which forms one of the costly parts of winning copper in the ordinary manner. Finally, the casting of the anode plates is difficult and uncertain, and the electrolytic process itself is interfered with by the falling to pieces of the anodes before their complete solution.

Soluble anodes are, however, necessary in the ordinary electrolytic process, because the use of insoluble anodes leads to strong polarisation whereby the useful work of the electric current is reduced in very great measure. In the Siemens method this evil is overcome by adding to the decomposing copper-carrying solution another solution which takes up the oxygen set free at an insoluble anode, and thereby lessens the polarisation. For such a depolarising solution ferrous sulphate is used, which is changed, by the oxygen set free at the anode, into ferric sulphate. A lixiviant for the copper in the ore is thus obtained, at the same time, as ferric sulphate is capable of dissolving metallic copper, as well as the sulphides of copper.

Instead of the iron sulphates the chlorides, ferrous and ferric, were formerly used with similar results. In this method, however, there were insuperable practical difficulties, so that it was abandoned. The method of Dr. Hopfner differs essentially from that of Siemens, only in that no iron salts are used, but cuprous and cupric chlorides instead; besides the construction of the apparatus is different. The electrolyte used in the Siemens method consists of a solution of ferrous and cupric sulphates, with the addition of some free sulphuric acid to increase its conductivity. This liquid is continually added to the cathode chamber, where a portion of the copper is deposited by the electric current, after which the liquor passes down into the anode chamber, and is finally drawn off at the bottom of the latter.

During this passage downward the ferrous sulphate is changed into basic ferric sulphate; then by the action of the free sulphuric acid, coming from the decomposition of the cupric sulphate it is changed into neutral ferric sulphate, which by its greater specific gravity sinks down to the carbon rods or plates of which the anode is composed. The liquor drawn off has thus become poor in copper and consists of a solution of neutral ferric sulphate. This solution has the property of converting cuprous and cupric sulphides, as well as metallic copper, into cupric sulphate. The ferric sulphate is thereby reconverted into ferrous sulphate, while the oxygen set free oxidises the copper. This oxidation and solution of the copper can be completely carried out with many finely pulverised sulphide ores, even in an unroasted condition, by use of a solution moderately heated. With other ores, however, a moderate roasting of the pulp, by which the copper compounds are converted essentially into cuprous sulphide, must precede the solution of the copper.

The lixiviation of the pulverised ore by means of the decopperised and oxidised liquor is performed in long, narrow, shallow wooden troughs, in which the pulp is kept suspended by means of stirrers. The liquor coming from the electric cells is continually fed at the head of the trough, mixed with the necessary amount of pulp, and leaves the trough with the decopperised pulp at the other end. The solution is hastened, if necessary, by heating the lixiviant by means of a steam-pipe lying in the trough. The leached pulp is separated from the solution either by settling or by a filtra-

tion apparatus. The solution has now become rich in copper and deoxidised, and is fed anew to the electric apparatus. Thus is constituted a continuous process between the leaching of the ore and the electrolysis of the solution, the lixiviant being produced electrically in the decomposition cells and the electrolyte regenerated chemically by the solution of the copper in the ores.

For the successful operation of this process it is necessary that it be carried on continuously night and day. The dynamo should be driven by its own motor in order to secure the most even possible running.

The cost of a plant for the production of 1,000 kilos. of pure copper per 24 hours, for ores containing from 4 per cent. to $4\frac{1}{2}$ per cent. copper, not including buildings, motive power, or foundations, is estimated as follows:—Electrolytic plant, 115,308 marks; ore crushing plant, 31,152·50 marks; leaching plant, 61,140 marks; total, 209,600·50 marks. With ores rich in copper the cost of the crushing and leaching plants is less inversely, as the grade of the ore. The size and number of the electrolytic vats, &c., is the same, whether the ore is rich or poor.

In the above estimate the electrolytic plant includes dynamos capable of precipitating 1,040 kilos. of copper per day, measuring instruments, conductors, 1,200 anodes, and the fittings for 100 baths. Also the following apparatus constructed at the proposed works: 100 wooden boxes (baths), 4,970 mm. long, 1,620 mm. wide, and 370 mm. deep, inside measurement, lined with asphalt; 5 wooden boxes (leaching vats), of 2 cb. m. contents, lined with asphalt; about 500 m. of wooden launders, lined with asphalt, 100 mm. wide and 100 mm. deep; 1,200 wooden slabs (cathodes), 1,520 mm. long, 400 mm. wide, and 25 mm. thick, without the copper plates; 600 wooden gratings (filters), 1·6 m. long, 0·815 m. wide, and 15 mm. thick, made of staves 25 mm. wide, together with 900 square metres of linen; 100 wooden gratings (stirring apparatus for the baths), 4,700 mm. long, 1,560 mm. wide, 20 mm. thick, made of staves 25 mm. wide.

The leaching plant consists of 16 wooden vats, with the stirring apparatus, 4,500 mm. long, 750 mm. wide, and 1,000 mm. deep; one wooden vat, lined with asphalt, for fresh liquor, nine iron vacuum chambers of 3 cb. in. contents, lined with lead, for half-regenerated lixiviant, and three of the same size for regenerated lixiviant; 10 wooden settling basins, lined with asphalt, $2 \times 2 \times 2$ metres; 100 wooden launders, 100 mm. \times 200 mm.; vacuum pumps, stirring apparatus, pipe fittings, filters, &c. The power required for the leaching plant is estimated at 10 h.p.

The crushing machinery, figured in this estimate, consists of three patented ball mills, with a capacity of comminuting 25 tons of ore to the necessary size per 24 hours. The estimate also includes the conveyors, elevators, and other appurtenances. For this part of the plant 45 h.p. is required.

The cost of producing 1,000 kilos. of fine copper per 24 hours, from 4 per cent. to $4\frac{1}{2}$ per cent. ores, is estimated as follows:—Interest on the capital invested in the plant (209,600 marks), at 5 per cent. per annum, 28·75 marks; amortisation of plant, at 10 per cent., 57·50 marks; motive power (130 h.p.), 62·40 marks; labour, 15 men, at 2 marks per man per day, 30 marks; interest on the copper in the baths, 10 marks; fuel for warming the lixiviant, 10 marks; general expense, superintendence, &c., 40 marks; total, 238·65 marks, exclusive of the cost of ore.

The cost of producing 1,000 kilos. of fine copper from ores rich in copper, copper matte, with 35 per cent. Cu for example, is estimated as follows:—Interest on the capital invested in the plant (160,000 marks), at 5 per cent., 22 marks; amortisation, at 10 per cent., 44 marks; motive power (85 h.p.), 40·80 marks; labour, 12 men at 2 marks, 24 marks; interest on copper in the baths, 10 marks; fuel for heating the lixiviant, 10 marks; general expenses, superintendence, &c., 35 marks; total, 185·80 marks.

PATENTS.

Improvements in Ozone Apparatus. Siemens Bros., London. From Siemens and Halske, Berlin. Eng. Pat. 8929, May 26, 1891.

THIS invention relates to improvements in tubes or apparatus for ozonising air. The electrical arrangement of such apparatus has hitherto consisted in interposing between two conducting coatings charged with electricity of opposite sign, one or two dielectric layers and the layer of gas to be ozonised, but according to this invention both the electric coatings are situated on the same side of the dielectric layer and separated by a shield of insulating material; while at a small distance from the other side of the dielectric layer is situated an insulated conducting plate. Thus currents will pass from the part of the dielectric layer below the one electric coating, through the narrow space in which the gas to be treated is situated, to the insulated plate, and from this back again through the gas to the part of the dielectric layer beneath the second coating.—G. H. R.

Improvements relating to the Electrolytic Extraction of Metals and to the Electrolysis of other Substances. C. Hoepfner, Giessen, Germany. Eng. Pat. 9079, May 28, 1891.

THIS invention consists in the use of ferro-silicon for anodes in electrolysis wherever expensive carbon or platinum plates have hitherto been employed. It is well known that this material has already been used by Uelsmann for the cathodes in Bunsen batteries, but this use is restricted to batteries having nitric acid as an exciting liquid, in circumstances where a preserving effect of the electric current is presumed.—G. H. R.

Improvements in or Appertaining to Accumulators for the Storage of Electric Currents. W. P. Thompson, Liverpool. From E. Correns, Berlin. Eng. Pat. 16,270, September 24, 1891.

THIS invention consists in the production of electrodes for secondary batteries by mixing with the active material the silicate of a metallic earth in order to cause the whole to set to a stone-hard mass, with the object of effectively preventing the crumbling and breaking away of the plates. To render the adherent mass porous, so as to afford access for the current to the interior, some substance such as zinc, which will subsequently dissolve out, is added to the mixture of lead salts and the alkaline silicate. Antimony, or tin also, may be employed, since they dissolve under the action of the current.—G. H. R.

Improvements in the Manufacture or Production of Chlorine and Alkaline Carbonates. C. Kellner, Vienna, Austria. Eng. Pat. 20,713, November 27, 1891.

See under VII., page 523.

Improvements in the Method of Purifying Electrolytes containing Zinc, relating to or connected with the Electro-metallurgic Production of Zinc. Nahnson, Cologne, Prussia. Eng. Pat. 2225, February 5, 1892.

ZINC has been employed in the form of chips or grains with the object of purifying electrolytes containing zinc, but this treatment is insufficient, and the present invention relates to its employment in the form of powder. When rough zinc, or alloys of zinc, have to be refined and are used as anodes in the baths, the resulting lye is always neutral or slightly basic, and is at once passed into the purifying apparatus where it is treated with zinc powder to free it from impurities, after which it is again ready for use in the baths. When the anode is insoluble, however, and the electrolyte consequently acid, it must first be neutralised by the addition of an ore containing the oxide or carbonate

of zinc, or any other raw material containing zinc in a readily soluble form, before it is passed into the purifiers, which consist of flat vats kept constantly stirred. When the impurities consist of copper only and amount to 1 per cent. of the entire quantity of zinc 10 lb. of copper must be precipitated by means of zinc powder in the daily production of 1,000 lb. of zinc, which will necessitate a daily addition of 11 lb. of zinc. It is preferable to introduce at the beginning of the operation a larger quantity of zinc powder into each vat, say 100 lb., and subsequently add the amount required daily to the first of the series. 1 per cent. of silver will require a daily addition of 5½ oz. of zinc for the same output of zinc.—G. H. R.

Improvements in Process and Apparatus for Bleaching by Electrolysis. O. Imray, London. From T. Y. Montgomery, New York, U.S.A. Eng. Pat. 2329, February 6, 1892.

THE invention consists in using sea water, or a solution of rock salt or sea salt of the same density, as the electrolyte, and providing means whereby air may be driven through the bath, thereby aiding the process of oxidation and bringing the products of electrolysis into better contact with the fibre or fabric to be bleached. The electrodes, which are perforated, are arranged horizontally in the bath, and the conductors and connections are coated with paraffin or other similar substance to protect them.—G. H. R.

Improvements in the Electro-Metallurgic Extraction of Zinc. G. Nahnson, Cologne, Prussia. Eng. Pat. 2913, February 15, 1892.

THE improvement consists in using an electrolyte composed of a mixture of the sulphate of zinc with a sulphate of the alkalis, but preferably not magnesia, and heating the bath to a temperature of about 130° F. The solution contains from 1½ to 2½ ounces of crystallised sulphate of zinc, and 10½ to 5½ ounces of a sulphate of an alkali per litre according to the density of the current. The following advantages are claimed for this process: that the conductivity is 300 to 400 per cent. higher than that of the sulphate of zinc electrolyte at the degree of concentration yielding the best conductivity, that any density of current from 8 to 125 ampères per square yard can be employed, and that using condensing engines it is possible to extract a ton of zinc from the ore with a consumption of only 3 to 3·5 tons of coal.—G. H. R.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

Occurrence of Octylic Alcohol in Distilled Wool Fat. C. Hannau. Pubbl. del. laborat. chimico centrale delle Gabelle. Roma, 1891; Chem. Zeit. Rep. 1892, 16, 2.

THE author thought Guetta's statement that octylic alcohol occurred in distilled wool fat, as a special characteristic thereof, might lead to a method of discovering adulterations practised with wool fat upon other fats. He was, however, unable to prove the presence of any such alcohol in distilled grease, and so cannot support Hannau's observation and statement (this Journal, 1892, 138).—J. L.

Testing Lard for Fatty Oils. P. Welhans. Pharm. Zeit. 36, 798; Chem. Zeit. Rep. 16, 4.

PATENTS.

Improvements in the Manufacture of Detergent Powder. R. Armstrong, Preston. Eng. Pat. 8827, May 25, 1891.

THE invention consists in adding to a mixture of sodium carbonate and soap or grease certain quantities of ammonia salts in crystals, or if the mixture of the materials in a hydrated condition, is to be made, the ammonia salts are to be protected by a coating of fat, stearin, or paraffin wax, so as to "prevent chemical contact with the alkali of the detergent powder." There are no less than eight claims, one of which protects the perfuming of such detergent powder.

—J. L.

Improvements relating to the Purification of Fatty Substances. H. H. Lake. From "La Société anonyme des Parfums naturels de Cannes," Paris, France. Eng. Pat. 9431, June 3, 1891.

IN previous specifications (Eng. Pats. 10,280, 1889, and 5940, 1890; this Journal, 1890, 325; 1891, 159), the use of steam and of a vacuum had been patented for purifying fatty substances extracted by volatile solvents, but these two methods have the drawback that a small quantity of water was retained by the fatty mass, whereby the latter acquired a dim appearance. This is avoided by the new patented method, according to which the fatty substance is heated—by means of a coil or a double bottom—up to a temperature higher than the boiling point of water under the pressure existing in the vessel.—J. L.

An Improved Filtering Apparatus for Oil and the Like. H. Berk, Chemnitz, Germany. Eng. Pat. 3052, February 16, 1892.

THE novelty claimed by the inventor consists in fixing two concentric casings in such a manner that a space is left between the outer casing and the inner one, which forms the filter proper; in this space all heavier impurities settle out before they can get on the filter. There is one sheet of drawings illustrating the apparatus.—J. L.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

Experiments to Determine the Effect of the Substances usually added to Caoutchouc and Gutta-Percha. C. Heinzerling and W. Pahl. Verhandl. d. Vereins zur Beförd. d. Gewerbe. 1891, 415, and 1892, 25.

NUMEROUS experiments on the hard and soft rubbers made from caoutchouc have given the following results. (By hard rubber is meant ebonite, vulcanite, &c.):—

1. All mineral and organic admixtures diminish the elasticity of soft rubber, the rubber mixture containing 10 per cent. of sulphur, used for vulcanising, yielded the most elastic product. The elasticity of hard rubber goods is, on the contrary, increased in certain cases by the addition

of organic substances, such as rosin oil and rosin, asphaltum, and such inorganic substances as vermilion, and lime.

2. The resistance to stretching of soft rubber is more or less increased by the addition of pitch, chalk, heavy spar, zinc oxide, and particularly magnesia. The addition of vermilion and magnesia has the same effect on hard rubber, as also has a longer vulcanisation with more considerable quantities of sulphur. All other mineral admixtures, such as litharge, hydrate of lime, and any organic mixtures (with the exception of a considerable addition of asphaltum), diminish the resistance of stretching in the cases both of soft rubber- and hard rubber-goods.

3. Mineral admixtures, as zinc oxide, lead oxide, chalk, magnesia, lime, and organic substances like asphaltum and glycerin, increase the solidity of soft rubber. The solidity of hard rubber is increased by the addition of large quantities of asphaltum, lime, or magnesia. Rosin oil and rosin in quantity diminish this quality. The solidity of soft rubber is diminished by the addition of linoleum, oil substitute, rosin oil, and paraffin.

4. Although pure rubber with sulphur has long been considered the best insulator, yet this is not so, as mixtures with a number of other substances answer better. These bodies are zinc oxide, lime, chalk, magnesia (in small quantities), antimony sulphide, also linoleum, oil substitute (in small quantities), rosin oil, rosin, and paraffin. The mixture of rubber and paraffin is the best. The addition of vermilion, lead oxide, and magnesia (in large quantities) diminishes the insulating power. The cold vulcanised rubber (so-called patent india-rubber) is the worst insulator.

5. All the mixtures of caoutchouc and organic substances give off vapours when exposed to heat (130°—150° C.). Rubber so prepared is badly adapted for standing exposure to heat. The other mixtures are not affected at these temperatures.

6. Most of the mixtures containing metallic oxides are attacked by acids, in many cases with the formation of insoluble metallic salts, which increase their weight. The mixtures of rubber and the already-named organic bodies resist acids well.

The power of resisting oil is increased by the presence of the already specified inorganic substances and especially of lead and zinc oxides. The action of alkalis and coal-gas is so slight that it may be ignored.

7. Most of the mixtures of caoutchouc and mineral substances become in time hard and brittle. Their insulating power does not, however, appear to become affected.

The experiments with various samples of gutta-percha have given the following results:—

1. The following bodies do not appreciably affect the action of chemicals on gutta-percha:—Vermilion, 50 per cent.; rosin and rosin oil, 15 per cent. each; lime (hydrate), 50 per cent.; asphaltum, 30 per cent.

2. Pure gutta-percha and pure "Ballata" (the dried juice of *Sapota Millerie Bleek*, gutta-percha substitute) without any addition whatever, form the best insulators.

3. The addition of other substances, as vermilion, lime, rosin oil, and rosin, diminishes the insulating power.

4. Asphaltum up to 30 per cent. has very little effect on the insulating power.

5. The resistance to stretching is somewhat increased by the addition of vermilion, 50 per cent., or lime (hydrate), 50 per cent. The limit of elasticity is diminished by these additions. The solidity is increased by vermilion and diminished by lime.

6. Rosin oil and rosin, 30 per cent., and asphaltum, 30 per cent., diminish the elasticity and hardness. These slightly increase the resistance to stretching.—A. L. S.

Note on the Spontaneous Conversion of Isoprene into Caoutchouc. W. A. Tilden. Chem. News, 65, 1892, 265.

ISOPRENE is a hydrocarbon which was discovered by Greville Williams many years ago among the products of the destructive distillation of india-rubber. Later, in 1884, (Trans. Chem. Soc. 45, 410) it was observed by the author

among the more volatile compounds obtained by the action of a moderate heat upon oil of turpentine and other terpenes. It is a very volatile liquid, boiling at about 36° . Its molecular formula is C_5H_8 , and it forms a tetrabromide, $C_5H_8Br_4$, but no metallic derivatives, like the true homologues of acetylene.

Bouchard (Compt. Rend. 87, 654, and 89, 361 and 1117), observed that when isoprene is heated to a temperature near 300° , it gradually polymerises into a terpene which he called di-isoprene, but which is now usually called *dipentene*. This compound boils at 176° . A quantity of eolophene similar to that which is produced by the action of heat upon turpentine is formed at the same time.

When isoprene is brought into contact with strong acids, aqueous hydrochloric acid, for example, it is converted into a tough elastic solid, which has been examined by G. Bouchardat and the author; it appears to be true india-rubber.

Specimens of isoprene were made from several terpenes in the course of the author's work on those compounds, and some of them were preserved. He was surprised a few weeks ago at finding the contents of the bottles containing isoprene from turpentine entirely changed in appearance. In place of a limpid colourless liquid the bottle contained a dense syrup, in which was floating several large masses of solid of a yellowish colour. Upon examination this turned out to be india-rubber. The change of isoprene by spontaneous polymerisation had not to his knowledge been observed before. The author can only account for it by the hypothesis that a small quantity of acetic or formic acid had been produced by the oxidising action of the air, and that the presence of this compound had been the means of transforming the rest. The liquid was acid to test paper, and yielded a small portion of unchanged isoprene.

The artificial india-rubber, like natural rubber, appears to consist of two substances, one of which is more soluble in benzene or in carbon bisulphide than the other. A solution of the artificial rubber in benzene leaves on evaporation a residue which agrees in all characters with a similar preparation from Para rubber. The artificial rubber unites with sulphur in the same way as ordinary rubber, forming a tough elastic compound.

The constitutional formula of isoprene is not known with certainty, but it must be selected from the five following formulae:—

It is obvious that compounds such as these containing doubly-linked carbon may polymerise in a variety of ways, but which way would lead to caoutchouc cannot be at present defined.—W. S.

Analysis of Linoleum Floorcloth. J. Pinette. Chem. Zeit. 16, 1892, 281.

See under XXIII., page 550.

Colour Testing. W. C. Wilson. Paper read before the Association of Master Painters and Decorators of Pennsylvania, U.S.A., per Chem. Trade J. 10, 130, 163, 274, 290.

The following points must be made the special features of colour testing:—

1. Purity of the material.
2. Purity of the tone; brilliancy, richness, which indicate the amount of care in selection.
3. Fineness of grinding or preparation; this signifies the degree of the division of the particles, and upon the completeness of such division will depend—
4. Its spreading capacity (covering power).
5. Its body. This of course applies to opaque or semi-opaque colours only. "Body" means capacity to conceal the surface to which the paint is applied and must not be confused with spreading capacity (covering power). It is an inherent quality.

6. Its staining power or tinting strength with white or other colours.

7. The quality or purity of the tint with white.

8. If a paste colour the consistency of the paste.

9. Transparency of transparent colours and the quality of transparency.

Sulphate of lime or silica are only adulterants when added surreptitiously to those articles in which they have no recognised place as components, as for instance, sulphate of lime in Venetian red and silica in ochre. White clay, or kaolin, is quite frequently used as an adulterant. Clay is a silicate of alumina and would occur naturally to a greater or lesser degree in ochre, sienna, amber, Vandyke brown, and earths generally. Carbonate of lime is found naturally in some of the earth pigments, but generally in very small quantities, and when found in quantities exceeding 5 or 10 per cent. must be considered an adulterant. Exceptions to this rule would be colours like rose pink, or all those lakes in which carbonate of lime is used as the medium for carrying the organic colouring matter. The same applies to the presence of barytes in pigments. Barytes, when mixed as oil paint, is absolutely devoid of opacity and covering power. When mixed with pigments that are specifically lighter, it will separate when painted, permitting the real pigment to come to the surface. Whiting and terra alba (sulphate of lime) are decidedly better oil absorbents than barytes. Zinc white, owing to its certainty to seal, will never replace white lead, though it may be desirable to use it in admixture with white lead.

GREEN PIGMENTS.—The green most used is that known as chrome green. It is prepared by mixing Prussian blue and chrome yellow, or by making the two together simultaneously. The commercial chrome greens consist of about one part of colour and three parts of mineral base, chiefly barytes. They may be divided into two classes, one inclining distinctly to yellow in tone and the other to blue. The difference is due almost entirely to the character of the chrome yellow in the green. For testing these greens three standards in three different shades of perfectly pure greens are used. By mixing two of them the shade of any chrome green sample can be perfectly matched. The sample to be tested is then reduced to one-tenth by mixing it with white lead. Next, 150 parts of white lead are weighed out and mixed in portions with the standard shade until the same depth of shade is obtained as that made with one-tenth of sample. The remaining part of the white lead is then weighed and found amounting to, say 30 parts, showing that 120 parts have been used to one part of the standard shade. This would show that the sample has but one-twelfth the colouring strength of the standard, or is approximately 8 per cent. strong.

To test the fineness of the greens, the colour is rubbed out on a piece of smooth glass with a palette knife; coarse particles show their presence by scratches. Chrome greens being a mixture of two colours are liable to show a separation of their elements when mixed very thin with oil of turpentine. The green showing this separation in the least degree is best in that respect. Body tests are made by equally thinning two samples with oil and painting them on well-primed boards of equal size.

Paris Green is distinctly crystalline in its character and its richness of colour depends entirely on this. In grinding, a Paris green must be selected of very fine crystal. Purity and quality must be determined comparatively. A ready test for purity is to dissolve out the oil with benzine and when the dry powder is obtained treat it with strong ammonia, in which it should be entirely soluble.

Verdigris is entirely a transparent colour. Like Paris green it is a copper compound and should be entirely soluble in ammonia.

REDS.—Venetian red, Indian red, Turkey red, rose pink, and red oxide, owe their colour wholly or in part to iron oxide, with the exception of rose pink and rose lake.

Indian Reds cannot be classed as pure, unless they contain from 95 to 99 per cent. of oxide of iron. The paler the Indian red, the greater the tinting strength and the rosier the tint; the deep coloured gives a purplish tint in comparison.

Tuscan Red is essentially a mixture of Indian red with some sort of lake colour, the cheapest article being made from a reduced Indian red and rose pink. The first quality of Tuscan red to be noticed is its brilliancy, next its opacity or body. Its tinting strength is of far less importance than the quality of the tint. Fineness of grinding must be insisted on. The best product of this class of pigments is the "new" Tuscan red, which contains the most permanent red lake colour known.

Venetian Red.—The best Venetian red is that one consisting of ferric oxide and sulphate of lime only. For a standard a red with 20 per cent oxide is best used. Its comparative brightness ought to be examined as well as fineness of grinding.

Vermilion.—This is a crystalline pigment. The deeper the shade the larger the crystal, hence the paler shade will have the more body. Although not brilliant it is the most reliable of all reds for permanency. The imitations are primarily orange lead coloured with eosine. Crimson tones are obtained by the introduction of white lead, zinc white, sulphate of lead, &c.; they are comparatively fugitive. Cheap grades are made with red lead and barytes.

Red Lead is quite an important pigment now. It is the very best preservative that can be applied in the shape of paint. It should never be mixed with whiting or similar bodies; where a mixture is desired equal parts of red lead and iron oxide will be found to give an excellent paint.

Yellow and Orange Chromes.—These colours are particularly susceptible to adulteration. In the pure state they are compounds of chromic acid and oxide of lead, or of chromic acid, sulphuric acid, and oxide of lead.

Pale Chromes.—The great desideratum is to get the minimum paleness of shade with the minimum of sulphuric acid, or with the maximum of chromic acid: that is, to obtain the minimum of paleness with the maximum of staining power. As the shade deepens, the strength lessens. This applies particularly to the orange chromes, which contain frequently orange lead. The presence of the latter is very objectionable, but is easily detected by the nitric acid test.

Medium Chromes ought to form clear golden tones with white lead and not a buff. A fourth or a third of zinc white mixed with the white lead used for these tints, has the property of holding the colour better. Adulterations of the medium chromes are found out by testing tinting strength in comparison with recognised pure standards. The pale shades ought not to incline to greenness, as such yellows will blacken very quickly. The grinding should be perfectly fine, without the faintest trace of grit.

Ochres.—The French ochres, which are the finest yet discovered, are regarded as the standard of quality.

Yellow Ochres.—These pigments owe their colour to hydrated oxide of iron. The other constituents are principally silicate of alumina, or clay and free silica. The value of an ochre does not depend on the percentage of ferric hydroxide. Gold ochre is invariably a mixture of ochre and chrome yellow. The standard of this should be a mixture of good French ochre with pure chrome yellow.

Blacks.—Bone blacks have generally some blue added, to intensify the colour. They vary greatly in colour and opacity, hence careful selection must originally be made. Lamp black improves the opacity of bone blacks, but is very injurious to their intensity. There is only about 10 per cent. of carbon in bone black, the rest being chiefly calcium phosphate.—C. O. W.

A Process for the Manufacture of White Lead. J. H. Noad, East Ham, Essex. Eng. Pat. 3832, March 3, 1891.

This invention relates to the production of white lead by electrolysis of a solution of acetate of ammonia, lead being used as anodes and any other conducting metal or carbon as cathodes.

An electrolytic bath is charged with a 10 per cent. solution of acetate of ammonia and in it are suspended as anodes, slabs, bars, or plates of lead. The cathodes, which may consist of any other conducting metal or carbon, are enclosed within porous cells or partitions, prepared of Willesden waterproof paper. These cells, as well as the bath itself, are provided with overflow pipes, which communicate with a pipe supplying carbonic acid gas and with a filter-press.

The bath is worked with an electric current of a density of about 4 ampères to the square foot and a pressure of about 1 volt to each tank. After a time the liquid in the porous cells is mostly ammonia, that of the bath being mostly acetate of lead. Through the mixed liquid overflowing from both, carbonic acid gas is blown, and the whole sent through the filter-press; the filtered liquid, containing the regenerated acetate of ammonia, is returned to the bath.—C. O. W.

A New or Improved Composition for Coating Ships' Plates and the Like. R. Jacks, South Shields, Durham. Eng. Pat. 9193, June 1, 1891.

A hot mixture of tar, pitch, and cement. The tendency of this mixture to set or harden is further secured by the admixture of litharge or other suitable dryer.—C. O. W.

Improvements in Paints or Protective Coverings for Ships' Bottoms and other Structures. C. H. Bigland, Liverpool. Eng. Pat. 2253, February 5, 1892.

In this invention a paint is proposed consisting of a boiled mixture of—

- 1 part of encre poison,
- 3 parts of Venice turpentine,
- 3 parts of sulphate of manganese,
- 6 parts of carbonate of lime,
- 6 parts of belladonna,
- 24 parts of ordinary pigment,

and sufficient oil or varnish to render the mass liquid.

—C. O. W.

Improvements in Spreading Machines for Spreading India-Rubber or other Plastic Material on Textile Fabrics and the Like. W. Coulter, Greenheys, and T. Rowley, Manchester. Eng. Pat. 3155, February 18, 1892.

The improvement relates to the gauges used on spreading machines and consists in three gauges swinging on the same pivots. The edges of these three gauges possess various degrees of sharpness, and being arranged as it were in the form of an equilateral triangle, the angles of which form the edges of the gauges, either of the latter is available for immediate use by turning the whole gauge round through an angle of 60°. Drawing attached to specification.—C. O. W.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

Contribution to our Knowledge of Sumac. W. Eitner.
Der Gerber, 1892, 18, 51.

THE author confirms Macagno's statement that the percentage of tannin in sumac leaves reaches a maximum and decreases afterwards. Macagno had shown that Virginia sumac contained in June, 21 per cent. tanning matter, whilst in August, 15 per cent. only were found. Eitner gives the following values for samac from Bosnia which was collected on the following dates: June 23rd, 18·97 per cent. tanning matter; July 7th, 22·97 per cent.; July 21st, 18·89 per cent.; August 4th, 17·17 per cent.; August 18th, 17·30 per cent.; September 2nd, 16·83 per cent.

The period at which the maximum of tanning matter appears in the sample from Bosnia is that before flowering, when all the leaves are completely developed. In Sicily the leaves are gathered at three periods: the lowest leaves are collected in May and gradually the upper leaves, when they have reached full development, are taken. Thus a product containing large quantities of tanning material (sometimes up to 26 per cent.) is obtained. American sumac reaches its maximum of tanning material (27 per cent.) in July; but as the leaves are gathered much later, namely before they become withered, the commercial product contains a considerably smaller quantity of tannin.

There is another advantage attending the gathering of the sumac leaves at the time of the tannin-maximum, since they tan a bright colour, while the over-ripe leaves contain a yellow-brownish colouring substance which makes its appearance only when the period of vegetation reaches its end. The same colouring matter also occurs in leaves gathered early, when they are exposed in a moist state to the action of sunlight, or if they are stored when moist. In the former case they lose at the same time some tannin; in the latter case, however, this does not occur, except when they grow mouldy. The Sicilians only have due regard for these properties of sumac, while in other countries, through the irrational methods attending the gathering, large sums are wasted. The government of Bosnia, assisted by the author, has started a rational system of culture of sumac.

Improvements in Drying Leather or Hides, and in Appliances therefor. E. Pim, Maghull, Lancaster. Eng. Pat. 6603, April 17, 1891.

LEATHER and hides have heretofore been dried by currents of air travelling in a more or less horizontal or upward direction, and in contact with both sides of the leather or hide. By this method damage has frequently occurred, especially to the grain, owing to the "variable and too energetic action of the air." By this invention the leather or hides are folded lengthwise, with the outer surface or grain within the fold, and suspended, belly edges upwards, in a closed chamber provided with holes disposed evenly through the ceiling and floor. Heated or dried air is drawn through the chamber downwards by means of fans or a chimney at the rate of a few feet a minute. Thermometers indicate the temperature of the air, and hygrometers its humidity. Valves serve to regulate the current of air, which is dried by quicklime. The drying of the leather or hides is thus effected from the flesh surface, and the grain protected.—A. G. B.

An Improved Process of Decolourising and Clarifying Tanning Liquors or Tannic Extracts. A. Huillard, Paris. Eng. Pat. 7106, April 24, 1891.

THE liquors (which mark on an average from 2° to 3° B.) from the tubs or vats of the exhausting batteries are treated "by a certain quantity of a derivative of strontium, such as strontium hydrate, anhydrous strontia, strontium carbonate, or other strontium salt." The effect of this treatment is claimed to be the precipitation of the colouring matters in the liquor. Filtration and the addition of a little sulphuric acid to precipitate the excess of strontia follow. A further filtration and concentration in a vacuum to 20° or 30° B. complete the process.—A. G. XV.—MANURES, Etc.

The Phosphate Beds of Florida. A. Keller. Chem. Zeit. 1892, 16, 65, 78—79, 110—113.

THE first portion of the paper deals with the climatic, geographic, and economic conditions which subsist in Florida, and influence the production and exportation of phosphates: this part may be dismissed as of commercial interest rather than chemical. The detailed consideration of the various kinds of phosphate follows and is here abstracted.

River-pebble is found in many of the rivers of West Florida, especially the Peace and the Alafia, and where it is abundant it is the most easily obtained phosphate. The sand and pebbles are raised by a dredging machine with a powerful centrifugal pump and thrown on to a revolving sieve made of iron bars and turning in an inclined plane. The pebble, sandstone, and sticks are retained by the sieve, the sand falling back into the river, and are immediately transferred to the drying apparatus. The quantity thus raised in a day varies with the locality; 100 tons may be pumped one day and only 20 the next, some parts of the river containing much phosphate, others containing little else than sand. The drying systems are three:—(1.) The brick-dryer, which is very similar to a pyrites burner; this does the work best, but is the most costly. (2.) The revolving dryer, an iron cylinder which is kept in rotation and through which the furnace gases pass. (3.) The screw dryer, which continuously passes the phosphate through the furnace. The cost of raising river-pebble averages 1 dollar per ton; during the current year this has been added to by the imposition of an *ad valorem* tax ranging from 50 cents to 1 dollar per ton. In certain parts of the Peace there is a greater tendency for phosphates to deposit than in others, and when such a spot has been dredged it may frequently pay to return to it sooner or later; in some

places the phosphate bank will leave the spot entirely during a flood and be deposited elsewhere. The exhaustion of the phosphate in the river Pease may be expected at no distant date; between April 1890 and September 1891 42,000 tons left by ship and 19,000 tons by rail.

Land-pebble.—Pebble phosphate consists of stones varying in size from the barely visible to that of a nut; in shape they resemble peas and beans; the angles are rounded and the surfaces polished. The river-pebbles are dark grey, bluish or black, a colour which they owe to tannin washed from the plants in the rivers; the land-pebbles differ from the river-pebbles only in that they have not been recently washed and are lighter in colour, being frequently white. In composition there is no difference between land- and river pebble; their average contents of calcium phosphate and iron and aluminium oxides are 65–70 per cent. and 3 per cent. respectively. River-pebble in the market does not contain more than 60–65 per cent. of calcium phosphate, as a rule, owing to the admixture of sandstone and sticks.

All the land between the Pease and Alafia creeks is more or less phosphatic. The richest district is an area of some 160 square miles between Bartow, Fort Meade, Chicora, and Callsville; the soil of this portion is sandy and covers a phosphatic clay. The following analyses of three borings are instructive:—

I. Cypress marsh on Chiloechatchee: Black mud, decaying wood, &c., 3 ft.; sand, 4 ft.; blue clay, with $2\frac{1}{2}$ lb. of white pebbles, 4 ft.; sand free from phosphate, 1 ft.; sand with $1\frac{1}{2}$ lb. of gray pebbles, 3 ft.; sandstone.

II. Cowbridge on Horsecreek: Humus, $\frac{1}{2}$ ft.; sand, 1 ft.; sand, with $4\frac{1}{2}$ lb. pebbles, 4 ft.; clay without phosphates, 10 ft.

III. 14 miles west of Bartow: Sand, 2 ft.; sandstone, 2 ft.; sandstone containing pebble, 1 ft.; white and green clay, with 25 lb. of white and green pebbles, 20 ft.; clay without phosphates, 5 ft.

Prospecting a pebble bed is easily accomplished with an ordinary clay-borer, but very erroneous estimates as to the quantity of phosphates are frequently made because of the necessity for passing through the ground-water which is nearly always near the surface; the clay gets churned up with the water, and if the phosphates be reckoned as a percentage on the bored-out clay the estimate for the bed will be too high. The author quotes a case in which his estimate for a bed was 15–20 per cent. of phosphate, while that of the American engineers, unaware of this pitfall, was 50 per cent. The use of 4-in. iron tube-borers, which are kept pumped out and not worked more than is necessary, is recommended.

An analysis of a section of the core of boring III., mentioned above, gave the following percentages on the dry substance:—Loss on ignition, 0.79; P_2O_5 , 33.61; CaO, 48.04; Fe_2O_3 , 1.20; Al_2O_3 , 1.38; MgO, &c., 5.54; CO_2 , 2.29; SiO_2 , 7.15. The top pebbles are frequently mixed with, or imbedded in, sandstone; but beyond a certain depth they are nearly always free from sandstone, and the deeper they are the better they seem to be; the white nodules containing much alumina seem to be for the most part at the top.

The land-pebble industry is still in its infancy, being but two years old. Improved machinery is wanted; the present washing machines perform their work very perfunctorily and leave too much alumina in the form of clay, rendering the phosphate practically useless. Failing a better method, some works dry the whole material and then sift out the sand and powdered clay; the phosphate obtained, however, is too aluminiferous for the European market. It has been found that many of the pebbles have been lost by the use of too coarse a sieve: one of 22 meshes to the inch gave in several experiments 25 per cent. more phosphate than one of 12 meshes. Although this particular kind of phosphate has not yielded much return as yet, great things are expected of it, mainly because it can be won entirely independently of manual labour. It may be noted that recent experiments to apply the dredging method used for river-pebbles proved abortive.

Hard-rock is as geographically distinct from pebble phosphate as it is mineralogically. South of Alafia Creek

pebble has the monopoly, while northwards hard-rock is almost the sole representative. The best of it occurs in "boulders," varying from several tons to several pounds in weight; these are embedded together with "gravel" in sand, clay, or the "soft-phosphate," described below. The depth of the beds varies from 40–50 ft. to 5–10 ft.; experimental boring has shown their extension at 60–65 ft., but, except where they outcrop, beds which are deeper than 10 ft. or 15 ft. have not been generally worked. The market phrase "land containing so much per cent. of phosphate" means that under 100 acres of such land there are so many acres in which the phosphate is covered by not more than 15 ft. of sand; on this scale of valuation 3 per cent. land is good and 5 per cent. very good. Prospectors' rules, such as "Where hammock—no phosphate" or "Where saw-grass—phosphate" are rare, but have only local significance, if any at all. The distinction between solid and laminated rock has reference to the greater homogeneity of the former, which is either white, grey, yellow, or, less frequently, dark blue or black; most frequently it is marbled and not all of one colour.

Good hard rock contains from 77 to 82 per cent. of calcium phosphate and 3 per cent. of ferric oxide and alumina. A detailed analysis gave, per cent.:—

H_2O 0.92; CaF_2 4.40; $Ca_3(PO_4)_2$ 85.14; $CaCO_3$ 3.63; Al_2O_3 1.52; Fe_2O_3 0.45; SiO_2 4.13.

Formerly hard rock only was exported, and the gravel was voted to contain too much alumina to be of use; but the latter is now washed, after which it contains 30–35 per cent. of phosphoric acid and seldom more than 3 per cent. of ferric oxide and alumina. This also applies to the laminated rock which contains pockets of clay amounting to some 5–8 per cent.; it is now burnt to make it brittle, broken, and sifted; this reduces the ferric oxide and alumina to 3–4 per cent. and renders the phosphate fit for export. In America phosphate can be marketed with much higher contents of ferric oxide and alumina than the European purchaser will tolerate. The burning of the rock is carried out by piling 100–200 tons to a height of 3–4 feet on a layer of wood one foot high and igniting; the method is cheap but otherwise unsatisfactory, and in the author's opinion practically useless.

Some details as to the methods of raising the rock, and a discussion concerning the respective merits of various cranes and scrapers here follow.

Plate-rock or **sheet-rock** is the most interesting of the Florida phosphates. It occurs in irregularly shaped tables of varying area, but most frequently about the size of a man's hand; they are one or more centimetres thick, and vary in colour from brownish yellow to white. The heavier and more brittle pieces are the richer in phosphoric acid, the lighter and softer contain more clay. The average contents of calcium phosphate is 74–78 per cent., and that of ferric oxide and alumina 3–4 per cent. and more; the latter however is due to the admixed gravel. Plate-rock always rests on the irregular surface of a stratum of limestone which is frequently dolomitic and contains remarkable "wells." These wells are nearly circular and 10, 12, or 15 metres deep; they are sometimes as much as one metre in diameter, and are filled with the same plate-rock, embedded in sand or clay, which forms the whole bed. In good places the phosphatic bed will contain 50–80 per cent. of plate-rock and is covered by 6–10 feet of sand. The mining is considerably easier than in the case of hard rock but the yield per acre is much less.

Plate-rock has been mined for some year and a half, but very little has found its way into the market; washing has proved difficult and capital has not been plentiful.

Soft phosphate is a phosphatic clay or clayey phosphate which is friable and easily worked; it is white, reddish or yellow, and contains varying quantities of water. The following analyses are put in:—

(1.) Soft phosphate from Polk county contained, per cent.,— H_2O , 8.35; total P_2O_5 , 29.80; water soluble, P_2O_5 , 0.81; citrate soluble P_2O_5 (after Wagner), 2.05; ditto (after Petermann), 2.83; Fe_2O_3 and Al_2O_3 , 8.86.

(2.) *Soft phosphate* from Alafia creek contained per cent., H_2O , 5.8; total P_2O_5 , 19.94; water soluble, P_2O_5 , 0.62; Fe_2O_3 , 7.50; Al_2O_3 , 10.26.

Much swindling is done in Florida with this soft phosphate. Certified by jerry analysts to contain 10 per cent. and more of water-soluble phosphoric acid, it is offered and purchased as a "complete fertiliser" at 30—35 dols. per ton, and as "raw soft phosphate" at 5 dols. In reality it is dear at any price, and what value it has as a manure can only be reaped by the farmer who can dig it for himself; it is not worth transport.

Pebble land in Florida will fetch 15—50 dols. per acre; for hard rock land 25.50, and 100 dols. are paid; the value of unphosphatic land is 3—5 dols.

The production of phosphate in Florida will not compare with that of South Carolina. The cost of winning should be reduced by improved machinery; lower rates of transport and wages are badly wanted. The author estimates the cost of mining at 4 dols. for good hard rock, 3—5 dols. for plate rock, and 1—2 dols. for river pebble (this Journal, 1891, 393 and 737; also 1890, 565).—A. G. B.

Sulphuric Acid Manufacture in 1891. R. Hasenclever. Chem. Ind. 1892, 15, 69.

PATENTS.

Means of Colouring Liquid Weed Destroyers, Sheep Dips, Insect Destroyers, and other Poisonous Liquids. T. Reade, Wolverhampton. Eng. Pat. 7569, May 1, 1891.

THE object of colouring such liquids as are detailed in the title is the prevention of accidents and crime; it is attained "by the introduction of a chromium compound, or compound of which chromium forms a part, to such preparations when of an alkaline character, or, when such preparations are not alkaline, but are compatible with an alkali, by the introduction of such compound and of an alkali."—A. G. B.

Improvements in the Manufacture of Artificial Manure. A. Knorre, Wandsbek-Marienthal, Schleswig-Holstein, Germany. Eng. Pat. 8402, May 15, 1891.

THE invention relates to the mucous refuse of tanneries, particularly from the fleshing and unhairing shops. This refuse is stated not to have been successfully employed heretofore for agricultural purposes when received direct from the tanneries, partly "on account of its great beating properties," and partly because it is liable "to form an impermeable felted cover on the land," in consequence of its constituents being principally hairs and "mucous parts."

The refuse is dried, first by draining or in a centrifugal machine, and then in a kiln. When dried it is ground in a "mill course," crushing mill, or other disintegrator. The hair having been made brittle by the action of the lime during unhairing and the subsequent drying, will readily grind up together with the other matter to a fine powder. If this powder is to be used directly after grinding, it is better to add a mineral acid (preferably sulphuric) to the refuse before drying and grinding, for the lime is thus converted into gypsum, which hardens during drying and renders the grinding more easy. Moreover, as sulphate, the "lime will be more effective and appropriate for numerous soils than the carbonate of lime." The powder is easily distributed over the land, and will not felt.—A. G. B.

An Improved Insecticide and Fertiliser. H. H. Lake, Middlesex. From the Biolytic Gypse Company, New York, U.S.A. Eng. Pat. 3023, February 16, 1892.

THE "lime-mud" obtained during the manufacture of caustic soda by boiling soda ash or black ash of 48 per cent. strength (100 parts) with unslaked lime (40—60 parts) in a "suitable quantity of water," is dried and powdered. This constitutes the new insecticide and fertiliser; in the former capacity it acts by virtue of the caustic soda which it retains. It is sown broadcast, or "dissolved in water" and sprayed on to the trees or other plants infected.—A. G. B.

XVI.—SUGAR, STARCH, GUM, Etc.

Recent Inventions in the Beetroot Sugar Industry. E. O. von Lippmann. Chem. Zeit. 1892, 16, 500—502.

AMONG the most important points touched upon in this review are the following:—The use of animal charcoal in the manufacture of raw beetroot sugar is growing quite exceptional, being by degrees entirely replaced by the improved mechanical filters. Even in the refining industry the use of animal charcoal is falling off. The Steffen Systematic washing process for the direct production of white sugar in the beetroot sugar factory has been employed to some extent, but has not given the results which were anticipated. Some factories in Austria and Belgium have worked successfully in this direction with Drost and Schultz's process, but detailed and exact proof is wanting. The recovery of sugar from molasses is almost abandoned at present in raw sugar factories. In the refining industry the chief claims of Steffen have been declared invalid in Germany. Very ingenious and effective forms of apparatus have been constructed for drying "crystals" and "granulated." The production of after-products in refineries is reduced to a minimum, or altogether avoided, and the recovery of sugar from molasses has been given up in almost all German refineries.—A. R. L.

The Best Means of Valuing Raw Sugar. A. Herzfeld. Zeits. d. Ver. f. Rübenzuckerind. Chem. Zeit. 16 (Chem. Rep.), 114—115.

THIS lengthy paper (112 pages), which deals with the question from historical as well as technological and chemical aspects, contains several important and careful investigations, the following being the salient points:—

1. *Production of Raffinose in Beetroot Sugar Products, and its Influence on the Form of Sugar Crystals.*—Raffinose originates in the root without doubt, but the opinions hitherto broached as to the causes of its origin are by no means certain, and in some cases incorrect. It is present in stromtia after-products (rarely in first products) and molasses to the extent of 8—16 per cent.; in osmose-molasses to 8 per cent., and in many ordinary beetroot molasses and refuse products of the industry. Small quantities of raffinose may occur in first products of polarisation, 94—97, as well as in clean after-products, but its amount is usually below the limit (0.33 per cent.) which can be estimated by the inversion method. The raffinose formula: $S = \frac{0.5124 P - 1}{0.839}$; $R = \frac{P - S}{1.85}$, ought only to be applied to those products in which the presence of this substance is probable, since many products contain compounds which would be reckoned as raffinose, and which are produced either from the sucrose or invert sugar by overheating in the manufacture, and also by exposure to the weather; among these are saccharic acid and its salts; high polarising substances (dextran?) are often present, and fermentation derivatives of the organic constituents other than sugars frequently occur in molasses. To control the optical test, the copper method of Preuss is recommended. The mucic acid method serves as a qualitative

test for raffinose, but is frequently inadmissible (in the presence of calcium salts for example) for quantitative purposes, as is also Gunning's methyl alcohol method, because in this case invert sugar saccharates, &c., are also dissolved. The occurrence of elongated crystals is not a specific indication of the presence of raffinose.

2. *The Solubility of Sugar in Water; the Formation of Molasses; and the Melassigenic Effect of Raffinose.*—By very accurate experiments made in an apparatus capable

of maintaining the temperature to 0.1°C ., it was found that 100 parts of water dissolve 65.17 parts of sugar at 5.2°C .; 66.63 parts at 19.15°C .; 68.31 parts at 28.8°C .; 72.23 parts at 49.53°C .; 74.33 parts at 59.4°C .; and 82.76 parts at 99.45°C . From these the percentage solubility of sugar is calculated by the method of least squares, thus:—

$$y \text{ to } x^{\circ}\text{C} : y = 64.1835 + 0.13477x + 0.0005307x^2,$$

whence the following table is constructed:—

Temperature C.	0°	5°	10°	15°	20°	25°	30°	35°	40°	45°	50°
Percentage of sugar...	64.18	64.87	65.58	66.33	67.09	67.89	68.70	69.55	70.42	71.32	72.25

Temperature C.	55°	60°	65°	70°	75°	80°	85°	90°	95°	100°
Percentage of sugar...	73.20	74.18	75.18	76.22	77.27	78.36	79.46	80.61	81.77	82.97

The old tables of Scheibler and Flourens are, therefore, only partially accurate, and show differences amounting to 10 per cent. in certain places. The solubility of sugar is decreased by the presence of small quantities of salts (organic and inorganic), but increased by that of large quantities; whilst salts containing water of crystallisation decrease the solubility, easily soluble salts such as potassium acetate increase it. The same is true of mixtures of salts, but each salt appears to act as if it were alone, therefore, relatively small quantities of mixtures of easily soluble salts raise the solubility of sugar largely in concentrated solutions. Normal molasses is not a supersaturated solution of sugar, but a saturated solution of sugar in that of the other ("nichtzucker") constituents. When sufficient water is added to molasses to form a saturated solution of sugar if it were present, *per se*, this diluted molasses will dissolve fresh quantities of sugar. When small quantities of potassium acetate, potassium chlorate, &c. are added to saturated sugar solution, the sugar is partially precipitated but redissolves on addition of an excess of the salts; albumin, pectin, dextrin, and dextran behave in the same manner. Raffinose follows the same rule as the other "nichtzucker" constituents, but has much weaker melassigenic properties than all the other substances examined, even than potassium chlorate.

3. *Proposed Alteration in Calculating the Rendement (Estimated Yield) of Raw Sugar, with regard to the Organic "Nichtzucker," especially Raffinose.*—In France it has long been the custom, instead of multiplying the ash by five and deducting this from the polarisation in calculating the "rendement," to deduct four times the ash, twice the invert sugar, and 1.5 per cent. for loss in manufacturing, or for the money value, to deduct twice the organic "nichtzucker" constituents reckoned at 60 centimes for each per cent. The author considers it more accurate, instead of merely deducting five times the ash, to take into account all the non-sucrose constituents, for not only are all these substances melassigenic, but certain of them are produced by the over-heating and decomposition of the sugar, and not being in combination with the ash, their action is at present entirely ignored. It is proposed, since the effect of raffinose has not been accurately ascertained, to deduct twice the total non-sucrose constituents from the polarisation in the case of first products. The chief objection to this is that the amount of organic "nichtzucker" which being obtained by difference is dependent on the accuracy of the estimation of all the constituents, the most inexact estimation being that of the water. This is, however, overcome by employing a drying-oven with double walls of asbestos or inlaid glass, and salt water, or toluene (boiling point, 109° – 110°) as heating material. A new basis for the calculation of after-products is to be desired.—A. R. L.

PATENTS.

Improvements in the Manufacture of Candy. H. H. Lake, London. From W. P. Kirchhoff and J. W. Kirchhoff, New Orleans, U.S.A. Eng. Pat. 13,566, August 11, 1891.

WHEN a solution of cane-sugar and glucose is concentrated *in vacuo* to the consistence necessary to form "hard crack," the candy produced is hygroscopic; whilst when the evaporation is performed in an open vessel, much caramel is produced. The patentee claims to have remedied these objections by the following process:—The solution is evaporated *in vacuo* to a consistency below that necessary to form "hard crack," and finished in an open vessel heated either by steam or direct fire.

—A. R. L.

Improvements in and relating to the Production of Adhesive Substances Soluble in Water from the Gum exuded from Almond, Cherry, Peach, and other Trees. L. Kern. Hamburg, Germany. Eng. Pat. 21,370, December 7, 1891.

THE patentee claims a process for purifying and preparing the gums from the above-mentioned sources, prior to their application and use as adhesive substances.

The crude gum is ground, separated by boiling from earth and other impurities, and the meal steeped in water for 12–24 hours. The gelatinous mass is run into an autoclave, where it is exposed to the action of steam at a pressure of 15–90 lb. per square inch for $\frac{1}{4}$ –1 hour, and then filtered under diminished pressure through narrow woven cloths. The filtrate is evaporated at a moderate but uniform temperature, and the viscid product dried on galvanised or enamelled iron sheets previously greased; the finished product is hard and brittle, and possesses all the properties of genuine gum arabic.—A. R. L.

An Improved Coil for Feeding Syrup or Molasses into Vacuum Pans. H. Basanta, San Juan, Porto Rico. Eng. Pat. 3236, February 19, 1892.

THE coil is somewhat smaller in diameter than the vacuum pan, and is placed within it, preferably over the steam coil, to which latter it may be secured. It is perforated on its lower portion, and on that part outside the pan there is a pipe for steaming the coil, and another for introducing chemicals, such as "bloomer" or sulphuric acid, &c., into the pan. It is claimed that the feed is more regularly distributed over the pan by this coil, and is, in fact, so gentle and well divided in the masseuite that each crystal continues to develop and the formation of small grains of dust is avoided.—A. R. L.

Improvements in the Crystallisation of Saccharine and other Solutions. J. C. Mewburn, London. From "The Maschinenfabrik Grevenbroich," Grevenbroich, Germany. Eng. Pat. 8345, May 19, 1892.

WELL developed crystals are placed in a tank (or series of tanks connected by pipes), having a perforated bottom, a tube or channel below it, and a second tube above the layer of crystals. The tank is heated by a jacket, and a saturated solution, at the same temperature as that of the crystals, is introduced through the lower tube; the solution circulates through the crystals and passes off through the upper tube, the process going on continuously; during its progress cooling air or water is caused to pass through the jacket. By this means the solution is kept in constant agitation during the cooling, and the patentee claims that the invention provides a process whereby well developed crystals are obtained even from solutions of low value, and the secondary formation of fine grains avoided.—A. R. L.

XVII.—BREWING, WINES, SPIRITS, Etc.

On the Presence of Invertase in Wine and Beer. E. Donath. Chem. Zeit. 16, 1892, 459.

THE nitrogenous constituents of wine and beer are not definitely known, and it appeared probable to the author that one of them might be invertase. Quite recently A. Bau (Chem. Zeit. 1892, 16, 143; Chem. Rep. 1892, 16, 86), has determined the cupric reducing power of beer both before and after digestion with cane sugar. His results indicate the presence of invertase.

The author took 1 litre of white wine and concentrated it to $\frac{1}{4}$ litre, taking care to keep the temperature below 35° C.; the residue on treatment with ether yielded a colourless jelly in the ethereal layer; this should contain the ferment if present. The jelly was poured into strong alcohol, and the floccular precipitate separated on the filter, subsequently dissolved in water, and re-precipitated with alcohol. The purified substance in aqueous solution did not reduce Fehling's solution, but on digestion with cane-sugar solution it did; thus proving the presence of invertase. Two litres of beer were treated in the same way and with the same results.—A. L. S.

Softening Brewing Water and the Treatment of Hard Water containing Soda. T. Langer. Allgem. Ztschr. f. Bierbr. u. Malzfabr. 1892, 20, 4.

A BREWING water of 34.6° hardness, which yielded a beer of unpleasant colour, was softened according to Clarke's method with lime until it possessed a hardness of 18°. It was then found to be quite satisfactory.

In another case a water which, besides being very hard, contained sodium carbonate, was treated in the same way and the sodium carbonate rendered harmless by the addition of gypsum.—A. L. S.

Report on the Deplastering of Wine. Berthelot, Gautier, and Duclaux. Compt. Rend. 114, 152–155.

FOR many years plaster of Paris has been added to wines, not, however, without objections having been raised to its use. A recent French statute has fixed 2 grms. per litre as the maximum amount of potassium sulphate that shall be present in a wine.

In order to reduce the amount of sulphate to this, after the operation of plastering has been performed, a mixture of strontium tartrate and tartaric acid has been used, strontium sulphate and potassium acid tartrate being produced.

After this process it is unfortunately found that quite appreciable quantities of strontium tartrate remain in solution, even when the deplastering has only been partially performed.

Although the salts of strontium in such quantities are not known to be in any way harmful, yet it is quite possible that when taken in daily doses they might in time have some ill effect. Also as commercial strontium salts are almost invariably contaminated with barium salts, of which the poisonous properties are well known, the employment of any compound of strontium for the above purpose must be attended with not a little risk.

Taking everything into consideration, the committee appointed recommends that the French Academy of Sciences expresses its disapproval of the practice referred to.

—A. L. S.

PATENT.

Improvements in or Applicable to the Manufacture of Unfermented Wine. J. F. Henderson, Aberdeen, N.B. Eng. Pat. 1044, January 19, 1892.

ABOUT 84 lb. each of bruised Muscatel and Valencia raisins, the rind of 28 lemons, and 24 lb. ginger are extracted with 5 to 6 gallons of spirits of wine 10 overproof. After drawing off the spirituous extract the residue is extracted with water containing 2 oz. salicylic acid, the aqueous extract is boiled with 3½ cwt. cane sugar and lemon juice. When cool there is added to it the spirituous extract and about 12 oz. of caramel. It is diluted with boiled water until the gravity is reduced to 45° Tw. and clarified either by subsidence or finings. To make an unfermented sparkling wine, 4 oz. of the extract are taken for each reputed quart bottle, the bottle filled up with water and the mixture carbonated in the usual manner.—A. L. S.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A.)—CHEMISTRY OF FOODS.

The Action of Certain Liquids on Aluminium. G. Lunge. Eng. and Mining J. February 13, 1892, 206.

EXPERIMENTS were all made with commercial rolled sheet aluminium, 1 mm. thick, from the Neuhausen works, of the following composition:—0.44 per cent. combined silicon, 0.11 per cent. crystallised silicon, 0.25 per cent. iron; traces of copper; 99.20 per cent. aluminium (by difference). The sheet was cut up into strips of such a size that they could be conveniently introduced into the flasks serving for experiment. Each strip was freed from sharp edges by a file, and was thoroughly cleaned in order to lay bare a real metallic surface and remove the excessively compact surface produced by the rolling process. They were for this purpose treated, first with concentrated solution of caustic soda, then with water, then with dilute sulphuric acid, again with water, scrubbed with a brush and distilled water, rinsed with alcohol and dried in an oven. Three such strips were accurately weighed, hung by means of small holes, upon a glass hook, in such manner as not to touch one another, and introduced into the flasks containing the liquids to be tested. Each flask held about 400 cc. of liquid, and was closed by a cork through which passed the stem of the glass hook. After leaving the whole for six days at the ordinary temperature of the room, the strips were taken out, rinsed with distilled water, freed from any adhering alumina, by means of a soft brush, rinsed with alcohol, dried and weighed. The loss of weight was referred to the aggregate surface of the three strips (about 130 sq. cm.), and is in the following table reduced to 100 sq. cm. Each liquid was tested at least twice in order to guard against accidental mistake. In a few cases, where the nature of the liquids presented no special difficulties, the alumina was, moreover, determined gravimetrically in the liquid after the experiments, with results closely approximating those found by ascer-

taining the loss of weight of the aluminium. The following table gives the results of the experiments :—

Liquids Experimented upon.	Loss in Weight.			
	A.	B.	Average.	Reduced to a Surface of 100 sq. ct.
Ordinary claret	Mg. 4.1	Mg. 3.3	Mg. 3.7	Mg. 2.84
Ordinary hock	4.0	4.5	4.3	3.27

Coffee.....	0.6	0.7	0.7	0.50
Tea
Beer.....
4 per cent. boric acid solution	2.3	2.3	2.3	1.77
5 per cent. carbolic acid	0.1	0.5	0.3	0.23
1 per cent. carbolic acid	0.8	0.5	0.7	0.49
$\frac{1}{2}$ per cent. salicylic acid.....	7.3	9.2	8.3	6.35

In very few of the cases was any action outwardly visible. In the case of brandy and alcohol, where the quantitative action was extremely slight, the surface of the aluminium showed a few fungus-like excreescences, probably formed by alumina, and caused by accidental flaws in the sheet. Lübbert and Roscher found that alcohol, ether, and all similar liquids had no action at all on aluminium foils, so that the observation made by the author would appear to be due to an accidental cause. Only in the last case, that of a solution of salicylic acid, did the aluminium lose its bright surface and become dull.
